Computation of the Pearson correlation coefficient

The Pearson correlation coefficient can be computed in various ways. Using standardized scores, the population Pearson correlation can be computed as follows:

$$\rho_{XY} = \frac{\sum_{i=1}^N (z_X z_Y)}{N}$$

where z_X and z_Y are the z scores (i.e., standardized scores) for variables X and Y respectively, whose product is taken for each case, and then summed across all N cases.

Derived from the standardized equation, the Pearson can also be computed as follows, where the numerator is the covariance and the denominator is the product of the standard deviations. The denominator provides the standardization of the covariance, and in this sense, the Pearson correlation is essentially a standardized covariance.

$$\rho_{XY} = \frac{\frac{\sum_{i=1}^N (X_i - \mu_X)(Y_i - \mu_Y)}{N}}{\sigma_X \sigma_Y} = \frac{\sigma_{XY}}{\sigma_X \sigma_Y}$$

The computational formula for the Pearson is written as follows:

$$\rho_{XY} = \frac{N \left(\sum_{i=1}^N X_i Y_i \right) - \left(\sum_{i=1}^N X_i \right) \left(\sum_{i=1}^N Y_i \right)}{\sqrt{\left[N \left(\sum_{i=1}^N X_i^2 \right) - \left(\sum_{i=1}^N X_i \right)^2 \right] \left[N \left(\sum_{i=1}^N Y_i^2 \right) - \left(\sum_{i=1}^N Y_i \right)^2 \right]}}$$

The sample correlation is denoted by r_{XY} (or r , where the correlated variables are implied). The formulas for the sample correlation r_{XY} and the population correlation ρ_{XY} are essentially the same. The only difference is notational, where n is substituted for N . For example, the computational formula for the sample correlation is as follows:

$$r_{XY} = \frac{n \left(\sum_{i=1}^n X_i Y_i \right) - \left(\sum_{i=1}^n X_i \right) \left(\sum_{i=1}^n Y_i \right)}{\sqrt{\left[n \left(\sum_{i=1}^n X_i^2 \right) - \left(\sum_{i=1}^n X_i \right)^2 \right] \left[n \left(\sum_{i=1}^n Y_i^2 \right) - \left(\sum_{i=1}^n Y_i \right)^2 \right]}}$$

The sample correlation can also be computed as follows using the covariance and standard deviations, where the covariance of X and Y is the numerator and the denominator reflects the standard deviations of X and Y .

$$r_{XY} = \frac{s_{XY}}{(s_X)(s_Y)}$$

Unlike the sample variance and covariance, the sample correlation has no correction for bias.

As an example, in [Table 1](#) we have data from a hypothetical sample of 20 students who have been assessed on academic achievement (as measured by GPA, column 1, $M = 3.127$, $SD = 0.255$) and emotional intelligence (column 2, $M = 45.742$, $SD = 11.240$). Using the formula for the correlation coefficient which includes the covariance ($s_{XY} = 0.872$) and standard deviation terms, we find a correlation coefficient of approximately 0.304.

$$r_{XY} = \frac{s_{XY}}{(s_X)(s_Y)} = \frac{0.872}{(11.240)(0.255)} = 0.304$$

This coefficient reflects a slightly stronger relationship between emotional intelligence and academic achievement than found by [MaccAnn et al. \(2020\)](#) who found an overall effect of $\rho = 0.20$ in their meta-analysis of 158 citations.

Interpretations of the Pearson correlation

There are many interpretations that can be made from the correlation coefficient. The *sign* of the Pearson correlation denotes the direction of the relationship (e.g., positive or negative), and the *value* of the Pearson denotes the strength of the relationship. The Pearson ranges within a scale from -1.00 to $+1.00$, where -1.00 indicates a perfect negative relationship, 0 indicates no relationship, and $+1.00$ indicates a perfect positive relationship. The larger the correlation coefficient (in absolute value terms), the more interdependence between the variables is suggested.

The squared Pearson is the *coefficient of determination* and is interpreted in many ways, all of which are stating the same concept: the proportion of shared variance; the proportion of variance in X accounted for by Y (and vice versa); the proportion of variance explained; and the proportion of variance of X predicted by Y (and vice versa). While the coefficient of determination is interpreted as a proportion (and thus an $r^2 = 0.10$ is one-half of the shared variance of $r^2 = 0.20$), r cannot be interpreted similarly (i.e., $r = 0.10$ cannot be interpreted as one-half the relationship of $r = 0.20$).

Hypothesis testing

The Pearson correlation can be used as a descriptives statistic or as an inferential statistic. Inferences can be made to determine the extent to which a single sample correlation differs from zero (i.e., no relationship). An example would be to test if the correlation between age and income differs from zero. In this example, a correlation of zero would indicate there is no relationship between age and income. Inferences can also be made to examine the extent to which two (or more than two) independent sample correlations are different. An example of this test of inference would be the examination of the extent to which the correlation between age and income differs for individuals who have (as compared to do not have) a college degree. Tests of inference between two dependent correlations can also be computed. An example would be when multiple measures are taken on a sample, and the researcher wants to determine if the relationship between two of the measures differs from the relationship between two different measures. interested in more in-depth coverage of hypothesis testing with correlations are referred to any number of excellent resources (e.g., [Hahs-Vaughn and Lomax, 2020a,b](#); [Wilcox and Muska, 2001](#); [Wilcox, 2017](#)), in addition to encyclopedia articles “Statistical Inference: Frequentist Approaches” and “Statistical Inference: Bayesian Approaches” for coverage of hypothesis testing/statistical inference more generally.

Assumptions of the Pearson correlation coefficient

The Pearson correlation coefficient is a parametric statistic. As such, there are distributional assumptions associated with it. Specifically, a linear relationship between X and Y , in other words, a bivariate normal distribution, is assumed for the Pearson. When linearity is violated, the Pearson correlation is not robust ([Wilcox, 2017](#)), and more specifically, “highly not robust... even a single aberrant point can alter r , the usual estimate of ρ , by a large amount. One practical consequence is that an association can be masked even by a single outlier” ([Wilcox, 2004](#)). In addition to outliers, additional data features that can affect the magnitude of the Pearson correlation include non-linearity, restriction of range, the magnitude of residuals, and rotating points (i.e., the magnitude of the slope around which points cluster) ([Wilcox, 2016](#)). Pearson correlation coefficient of zero may occur even if there is a strong non-linear relationship. As a result of these limitations, a number of alternatives to the Pearson have been developed, some of which are more robust than others. Many of these alternative coefficients are presented in [Nonparametric Correlations](#) section.

Visualizing relationships

When X and Y are measured on at least an interval scale, scatterplots can be valuable in understanding the relationship between variables, both the strength and the direction. Using Cohen’s conventions for interpreting correlations as an effect size ([Cohen, 1988](#)), [Figs. 1–4](#) show examples of weak ($r = 0.10$), moderate ($r = 0.30$), and strong ($r = 0.50$) correlations. [Figs. 5 and 6](#) provide illustrations of very strong positive relationships ($r = 0.95$), and [Fig. 7](#) provides an illustration of a strong negative relationship ($r = -0.70$).

When $r = 0.10$ (see [Fig. 1](#)), there is a lack of definition to the points in the scatterplot. In other words, relatively no concentration to the points (seemingly random) and no identifiable trend to suggest either a positive or negative relationship.

In the case of a moderate relationship, such as $r = 0.30$ (see [Fig. 2](#)), the points in the scatterplot adhere a bit tighter together such that there begins to be a discernible relationship evident. In this case, with a positive correlation, as the values of X increase, the values of Y decrease. This suggests a positive relationship. Additionally, there is more definition in the figure such that the points are adhering more closely together in a pattern as compared to those in [Fig. 1](#), although there is still somewhat of a loose scatter to the points.

Fig. 1 Scatterplot ($r = 0.10$).

Fig. 2 Scatterplot ($r = 0.30$).

With a smaller sample size ($n = 20$ in Fig. 3, see data in Table 1; vs. $n = 200$ in Fig. 2), the scatterplot of the relationship between emotional intelligence and academic achievement ($r = 0.30$ in both Figs. 2 and 3) becomes somewhat more difficult to discern in terms of the direction and strength given the relatively looseness of points coupled with fewer points.

When $r = 0.50$ (Fig. 4), the concentration of points in the scatterplot is tighter, providing a better visual to understand the strength and direction (i.e., positive) of the relationship.

When $r = 0.95$ (Fig. 5), the concentration of points in the scatterplot helps the reader to understand the strength of the relationship (i.e., the tight concentration suggests a very strong association) as well as the direction of the relation (i.e., positive; as values on X increase, values on Y also increase).

Fig. 6 presents a scatterplot with variables again correlated strongly ($r = 0.95$). However, the scales for X and Y differ. X has a mean of 10 and standard deviation of 1, and Y has a mean of 30 and standard deviation of 5. Thus, even when the correlation coefficient is very strong, the scales of the variables may be very dissimilar. In other words, the metrics of the variables do not need to be similar to manifest a relationship.

A strong negative relationship is presented in Fig. 7. The negative relationship is reflected in the direction of the points; as the values for X increase, the values for Y decrease (and vice versa). The concentration of points in the scatterplot, while not as tight as those in Figs. 5 and 6, suggest a strong relationship between the variables.

Fig. 7 Scatterplot ($r = -0.70$).

Nonparametric correlations

There are a number of correlation coefficients that fall under the umbrella of nonparametric correlations. Nonparametric correlations have fewer associated assumptions as compared to parametric correlations. Some of the most common that we will discuss include: phi; Cramer's phi; Spearman; and Kendall's tau. Many additional alternatives to the Pearson are then also presented.

Phi coefficient

The phi coefficient, ρ_ϕ is an appropriate correlation to use when both variables being correlated are dichotomous in nature (i.e., binary categories coded as 0 and 1). The phi represents the geometric mean of the percentage differences across rows and columns in variables that are nominal in scale (Hernes, 1970).

When correlating two binary variables, consider a 2×2 contingency table as shown in Table 1. The columns correspond to the two levels of the first variable (coded as 0 and 1) and the rows correspond to the two levels of the second variable (again coded as 0 and 1). The cells within the contingency table indicate the frequencies for the particular combinations of the levels of the two variables. The phi is computed as follows (Pearson, 1904), where the letters represent the frequencies of the respective cells within the contingency table (see Table 2):

$$\rho_\phi = \frac{(bc - ad)}{\sqrt{(a + c)(b + d)(a + b)(c + d)}}$$

Table 2 Example contingency table.

X	Y		
	0	1	
1	a	b	a + b
0	c	d	c + d
	a + c	b + d	a + b + c + d

A perfect relationship for the phi occurs with either of the following conditions: (a) empty cells are present in either of the two diagonally opposite cells; or (b) the margins of each row and column are identical (e.g., $a + b = a + c$ or $b + d = c + d$).

The phi is statistically equivalent to the Pearson, and is thus considered a special case of the Pearson correlation. In comparison to Pearson which can range from -1.0 to $+1.0$, due to the binary nature of the data, the range for phi often does not reach -1.0 or $+1.0$. A challenge in using the phi is that the value of the phi coefficient is commensurate with the table marginals, with less precise results when the marginals are more unequal (Liu, 1980). Standardization of the table marginals has been suggested so that the phi coefficient can be applied to comparisons (Deming and Frederick, 1940). An iterative technique, for 2×2 and larger $R \times C$ tables, to standardize the table marginals and allow for cross-table comparison has been offered (Bonacich, 1972; Liu, 1980).

In addition to early work by Pearson (1904), readers interested in early discussions of the phi coefficient are also referred to Yule (1912).

As an example, correlating the binary measures of academic achievement (0 = below 3.000; 1 = above 3.000) and emotional intelligence (0 = below 50.000; 1 = 50.000 or above), we find a phi coefficient of -0.179 (see Table 3 for contingency table).

$$\rho_{\phi} = \frac{(bc - ad)}{\sqrt{(a + c)(b + d)(a + b)(c + d)}} = \frac{(5)(3) - (4)(8)}{\sqrt{(4 + 3)(5 + 8)(4 + 5)(3 + 8)}} = \frac{-17.00}{94.916} = -0.179$$

While binary (e.g., pass/fail, yes/no) and ordered categories (e.g., Likert scales) are common to find in practice, it is not recommended practice to force order continuous data into binary or ordered categories as information on the responses is lost in the process. Categorizing the values into dichotomous or polytomous ordered categories has been done within this article for illustrative purposes only. As seen here, this loss of information results in a different estimated correlation coefficient relative to what was computed using the Pearson correlation coefficient.

Cramer's V

Cramer's V is an appropriate correlation to use when the variables being correlated are multichotomous in nature (Cramér, 1946). Cramer's V can be computed when both variables are nominal (with at least one variable having more than two categories) or when one variable is nominal and the other variable is ordinal (and at least one variable has more than two categories). Although the chi-squared statistic and contingency coefficient can be computed in the same situations (in terms of measurement scales of variables) as Cramer's V, Cramer's V is the preferred statistic to compute (Chen and Popovich, 2011) (albeit challenges that exist as will be noted subsequently). Cramer's V can range from 0 when X and Y are unrelated, to $+1.0$ when at most one non-zero probability appears in every row or column (assuming non-zero marginal probabilities), and is computed as follows, where χ^2 refers to chi squared and $\min(\text{row}, \text{column})$ refers to the smallest number of rows or columns in the contingency table:

$$V = \sqrt{\frac{\chi^2}{n[\min(\text{row}, \text{column}) - 1]}}$$

There are challenges with Cramer's V. Likely most problematic is that Cramer's V has no meaningful interpretation; a large coefficient does not necessarily indicate a strong association, and likewise, a small coefficient does not necessarily indicate a weak association. As a result, several alternatives to Cramer's V have been proposed that offer meaningful interpretations (Goodman and Kruskal, 1979; Kvalseth, 2018). Cramer's V also has challenges in notation. While $\hat{V}^2$ was originally proposed by Cramér

Table 3 Emotional intelligence and academic achievement contingency table.

Emotional intelligence	Academic achievement		
	0 (below 3.0)	1 (3.0 or above)	
1 (50 or above)	a = 4	b = 5	a + b = 9
0 (below 50)	c = 3	d = 8	c + d = 11
	a + c = 7	b + d = 13	a + b + c + d = 20

(1946), this notation has not been universally adopted. Many software packages use V , but not all. Adding to the notation confusion is the squared canonical correlation coefficient, also noted as $\hat{V}^2$ (Kendall and Stuart, 1958).

Computationally, because χ^2 is an element in the calculation for Cramer's, small sample size and small cell frequencies that plague χ^2 are also problematic with Cramer's V . When small sample size and small cell frequencies are present for chi-squared, the approximation of chi-squared will be inaccurate and Cramer's V will be over or underestimated, leading to Type I errors (Kvalseth, 2018). Additionally, if either the number of rows or columns changes, small changes in proportions can create a substantial change in the Cramer's V coefficient (Kvalseth, 2018).

It was noted previously that Cramer's V can reach +1.0 given certain marginal probability values. When one or more marginal probabilities are zero, Cramer's V can be impacted. For example, Cramer's V may not reach +1.0 even if there is a perfect relationship and the number and rows and columns are the same (Kvalseth, 2018). Additionally, Cramer's V coefficients are only comparable in situations where the contingency tables which are being compared have the same values of $\min(\text{row}, \text{column})$.

As an example, correlating the binary measure of academic achievement (0 = below 3.00; 1 = 3.00 or above) and ordered category measure of emotional intelligence (5 categories), we find a Cramer's V coefficient of nearly 0.60 (specifically, $V = 0.577$):

$$V = \sqrt{\frac{\chi^2}{n[\min(\text{row}, \text{column}) - 1]}} = \sqrt{\frac{6.667}{20[2 - 1]}} = 0.577$$

In comparison, correlating the binary measure of emotional intelligence (0 = below 50; 1 = 50 or greater) and ordered category measure of academic achievement (4 categories), we find a slightly larger Cramer's V coefficient (specifically, $V = \sqrt{\frac{8.225}{20[2-1]}} = 0.641$). While binary (e.g., pass/fail, yes/no) and ordered categories (e.g., Likert scales) are common to find in practice, it is not recommended practice to force order continuous data into binary or ordered categories as information on the responses is lost in the process.

Spearman's rho

Spearman's rho rank correlation coefficient was proposed by Spearman as a correction for attenuation in Pearson's coefficient (Spearman, 1904), and is appropriate to compute when both variables are ordinal in scale. In his first discussion of this correlation, Spearman not only presented the first approximation of the coefficient but also decried the benefits of ranks, which included, among others, that this method is not influenced by outliers as happens in the case of Pearson's coefficient (Spearman, 1904).

The history of Spearman's rho is quite lively and scholars have noted that "no one really 'discovered' SRC [Spearman's rho coefficient], or perhaps at best that SRC somehow mysteriously emerged from the various bouts of fisticuffs between Spearman and Pearson" (Lovie, 1995). Lovie (1995) concludes that Spearman brought rank data to the forefront and provided the first discussion of Spearman's rho coefficient, while Pearson named Spearman's rho as ρ and explored the properties of the coefficient. Kendall, however, revived the coefficient in the late 1930s and early 1940s, repositioned it within nonparametrics, and named it Spearman's rho coefficient (Lovie, 1995).

Spearman's correlation is a measure of relationship of ranked data and can be computed as follows (assuming no tied ranks) (Hotelling and Pabst, 1936):

$$\rho_s = 1 - \frac{6 \left[\sum_{i=1}^N (X_i - Y_i)^2 \right]}{N(N^2 - 1)}$$

An example of a tied rank would be if two cases had the same value on either variable being corrected. When one or more ties in rank exist, this formula is only approximate, depending on the number of ties. Thus, when there are ties, especially when there are more than a few ties, many researchers recommend using Kendall's tau as an alternative correlation (e.g., Wilcox, 1995). Spearman's coefficient can also be computed via Pearson on the ranked X and Y .

Like the Pearson correlation, Spearman's rho can range in value from -1.0 to $+1.0$ indicating the degree of monotonic relationship between the variables. When the correlation is 0, there is no relationship in how the variables have their data rank ordered. A value of $+1.0$ indicates that the ordered points in the two variables are exactly the same. A value of -1.0 indicates that the ordered points in the two variables are exactly opposite (i.e., one data point ranking first in one variable and one data point ranking last in the other variable). The sign of the coefficient can be interpreted as with the Pearson. Negative correlation coefficients indicate that as the values for one variable increase, the values for the second variable decrease. Positive correlation coefficients indicate that as one variable increases in value, the value of the second variable as well.

Spearman's rho and Kendall's tau, both functions of rank, have been shown to correlate at least 0.98, approaching 1 as the sample size approaches infinity, when X and Y are independent (Kendall and Stuart, 1958).

Had the data in columns 1 and 2 of Table 1 (the continuous values) been treated as rank ordered (columns 3 and 4) instead of continuous, a similar relationship would be present with Spearman ($\rho_s = 0.263$) as what as computed using continuous data with Pearson ($r = 0.30$). If the data were ordered categories (columns 5 and 6 of Table 1), the Spearman coefficient weakens slightly ($\rho_s = 0.220$).

Kendall's tau

Kendall's tau (Kendall, 1938), τ , is also appropriate when both variables are ordinal in scale and is also computed from ranked data. With Kendall's tau, the values for one variable are rank ordered and then the order of the second variable is examined to see if/how many pairs of values are out of order. Kendall's tau can be computed as follows when there are no ties in rank (denoted as τ_a), where P represents the number of concordant pairs (i.e., agreeing) and Q represents the number of discordant (i.e., disagreeing) pairs. More specifically, with any pair of observations, (X_A, Y_A) and (X_B, Y_B) , the pairs are concordant if the sort order of the observations agree (e.g., $X_A > X_B$ and $Y_A > Y_B$ or $X_A < X_B$ and $Y_A < Y_B$). If the sort order does not agree, in other words, if the observations are in reverse order or opposite directions (e.g., $X_A > X_B$ and $Y_A < Y_B$ or $X_A < X_B$ and $Y_A > Y_B$), the pairs are discordant.

$$\tau_a = \frac{2(P - Q)}{n(n - 1)}$$

When there are ties, Kendall's tau- b can be computed. In this formula, P represents the number of concordant pairs and Q represents the number of discordant pairs. X_0 represents the number of paired observations that are tied only on X , and Y_0 represents the number of paired observations tied only on Y .

$$\tau_b = \frac{P - Q}{\sqrt{(P + Q + X_0)(P + Q + Y_0)}}$$

Kendall's is interpreted in the same fashion as Spearman's. When all scores of the two variables are ordered the same (i.e., no scores of the two variables are out of order), a perfect positive correlation (+1.0) is achieved. When scores of the two variables are in exact opposite order, a perfect negative correlation (−1.0) is obtained. When there is no relationship in how the variables have their data rank ordered, the correlation is 0. Negative correlation coefficients indicate that $P - Q$ is negative. Positive correlation coefficients indicate that $P - Q$ is positive. When tied ranks exist, Kendall's τ_b (Kendall, 1945) and Stuart's τ_c (Stuart, 1953), which are modifications of Kendall's τ_a , can be computed. When there are many tied ranks, Goodman and Kruskal's gamma correlation (Goodman and Kruskal, 1954) can be computed.

While Spearman's rho and Kendall's tau are similar in that they are both functions of ranked data, they are calculated differently. As such, it is not uncommon to find different results when calculating Spearman's and Kendall's tau. Kendall claimed preference for tau, relative to rho, for practical and theoretical reasons including a simpler interpretation for tau when estimating the population parameter (Kendall and Gibbons, 1990; Kendall, 1970). While both are appropriate when ordinal data are being correlated, Kendall's tau (as compared to Spearman's rho) better estimates the population correlation coefficient given sample data (Howell, 2010), especially when the sample sizes are smaller (e.g., $n < 10$). Kendall's tau has been shown to be more powerful than Spearman's rho for testing the null hypothesis that the correlation coefficient equals zero (van der Waerden, 1969).

Instances where the ordinal variables being correlated are affected by a third variable (e.g., blocking variable) have been discussed (e.g., Korn, 1984). In the presence of a blocking variable, the weighted sum of Kendall's tau or Spearman's rho can be computed. Simulation research suggests they are equally powered when using the optimally weighted sum of taus or rhos, but Spearman's rho is preferred when ties are present as its variance has a simpler form (Taylor, 1987).

Generalizations to Kendall's tau which allow the examination of dichotomous, ordinal, and quantitative measures have been developed (Zhang et al., 2010). Kendall's tau has also been applied to single-subject research designs as tau- U , correlating time and the observed outcome (e.g., Brossart et al., 2018), within Bayesian methods (e.g., van Doorn et al., 2019), and within multilevel models (e.g., Romdhani et al., 2014).

Table 4 presents the continuous and rank ordered data previously presented in Table 1, with the exception that academic achievement (continuous variable) has been rank ordered from the smallest to largest values. Had the data in columns 1 and 2 of Table 4 (the continuous values) been treated as rank ordered (columns 3 and 4) instead of continuous, a weaker correlation is evidenced with Kendall's tau ($\tau_b = 0.179$, where P represents concordant pairs and sum to 112, and Q represents discordant pairs which sum to 78) relative to what was computed using continuous data with Pearson ($r = 0.30$).

If the data were ordered categories (columns 5 and 6 of Table 1), which is common to find in practice, Kendall's tau weakens further ($\tau_b = 0.141$).

Additional alternative correlation coefficients

The correlations presented thus far are arguably the most common correlation coefficients. However, there are several additional correlations that can be computed which are more robust to violations of assumptions associated with the Pearson correlation. A concise overview for some of these lesser known correlations is presented. Readers interested in formula and technical notes are referred to the resources presented.

Percentage bend correlation

The percentage bend correlation is a correlation coefficient that can be computed when linearity is not a reasonable assumption (e.g., skewed distributions) (Wilcox, 1994). As one robust analog to the Pearson coefficient, the percentage bend correlation protects against outliers in the marginal distributions without taking the overall data structure into account (Wilcox, 2017). The percentage bend correlation is intended to serve as a correlation estimate that is not overly sensitive to minor distributional changes, and it is not intended to replace or serve as an estimate of ρ (Wilcox, 2017). An example of the use of the percentage bend correlation is in neuropsychological studies that have small samples due to rare disorders and often extreme observations (Kulesz et al., 2015).

Table 4 Concordant and discordant pairs for academic achievement and emotional intelligence scores.

Academic achievement	Emotional intelligence	Academic achievement (rank)	Emotional intelligence (rank)	Discordant pairs (Q)	Concordant pairs (P)
2.676	50.928	1.00	12.00	11.00	8.00
2.839	55.193	2.00	17.00	15.00	3.00

Point-biserial and biserial correlation

When the Pearson correlation coefficient formula is used with a dichotomous (0, 1) variable and a continuous variable, the correlation is known as a point-biserial correlation. The formula for the point-biserial correlation, as presented by [Sheskin \(2011\)](#), is as follows:

$$r_{pb} = \left(\frac{\bar{Y}_0 - \bar{Y}_1}{s_Y} \right) \sqrt{\frac{Np_0(1-p_0)}{N-1}}$$

Where $\bar{Y}_1$ represents the mean of the continuous variable for the cases coded as 1 on the binary variable, $\bar{Y}_0$ is the mean of the continuous variable for cases coded as 0 on the binary variable, and s_Y represents the sample standard deviation for the continuous variable. The overall sample size is N , with p_0 representing the proportion of cases coded 0 in the binary variable.

When the binary variable is generated by dichotomizing a continuous variable which originates from a distribution that is normally distributed, the Pearson correlation coefficient computed between these variables is termed the biserial correlation ([Cheng and Liu, 2016](#)). The biserial correlation is computed as follows:

$$r_b = \left(\frac{\bar{Y}_0 - \bar{Y}_1}{\sigma_Y} \right) \left(\frac{n_1 n_0}{\gamma N^2} \right)$$

The notation follows that from the point-biserial correlation. The new term, γ , represents a probability density, specifically the ordinate or height of the standard normal distribution curve at the point on the curve which separates p_0 (proportion of cases coded as 0) from $1-p_0$ (proportion of cases coded as 1). The sample sizes of the cases coded as 1 and 0 are reflected in n_1 and n_0 , respectively.

The biserial correlation coefficient can be computed from the point biserial as follows:

$$r_b = \frac{r_{pb} \sqrt{p_0(1-p_0)}}{\gamma}$$

In both cases, the biserial and point-biserial correlation coefficients are appropriate to compute when correlating a dichotomous (0, 1) variable with a continuous variable ([Tate, 1954](#)). Using the binary data for academic achievement and the continuous data for emotional intelligence from [Table 1](#) and applying the Pearson correlation coefficient, we compute a sample point-biserial correlation coefficient as follows:

$$r_{pb} = \left(\frac{\bar{Y}_0 - \bar{Y}_1}{s_Y} \right) \sqrt{\frac{Np_0(1-p_0)}{N-1}} = \left(\frac{45.947 - 45.360}{11.240} \right) \sqrt{\frac{20(0.35)(1-0.35)}{20-1}} = 0.026$$

Had the point-biserial correlation been computed using the binary data for emotional intelligence and continuous data for academic achievement (see Table 1), the point-biserial correlation coefficient would be quite a bit stronger, specifically 0.176. Thus, depending on the variable which is dichotomized, the point-biserial may produce similar results to other correlation coefficients.

Computing the biserial using the point-biserial for the relationship between the binary data for academic achievement and the continuous data for emotional intelligence, we find the following. In this case, using the standard normal curve table, the value of z that demarcates the upper 35% of the distribution (p_0) from the remaining 65% ($1-p_0$) is approximately 0.39. When z is 0.39, y is 0.3697 (where y is obtained from a table for ordinates of the standard normal curve such as Bernstein et al. (1988)). Accordingly, the biserial correlation can be computed from the point-biserial as follows:

$$r_b = \frac{r_{pb} \sqrt{p_0(1-p_0)}}{y} = \frac{0.026 \sqrt{0.35(1-0.35)}}{0.3697} = 0.034$$

Early scholars noted that the range of the point-biserial correlation never reaches the same value as the biserial correlation (Lord and Novick, 1968), specifically reaching a maximum of 0.798 when the continuous variable is normally distributed (Cheng and Liu, 2016). Thus interpreting the size of the point-biserial correlation based on the usual range of the Pearson correlation is discouraged (Allen and Yen, 1979). More recent research suggests that the point-biserial coefficient becomes more restricted when the probability that the binary variable is 1 (vs. 0) departs from 0.50. However, the maximum value of the point-biserial correlation may actually range from -1.0 to $+1.0$ (Cheng and Liu, 2016). Thus, researchers should not assume the point-biserial has a restricted range (Cheng and Liu, 2016). The point-biserial correlation is often used to calculate item-total score coefficients (i.e., how strongly each item correlates with the total score) as a way of estimating item discrimination.

Tetrachoric correlation

A tetrachoric correlation, denoted as r_t , is a special case of the Pearson coefficient. The tetrachoric coefficient assumes bivariate normality for two continuous latent variables measured as dichotomous (i.e., a 2×2 contingency table). When there is bivariate normality of the underlying distribution prior to dichotomization, the phi coefficient can be computed from the tetrachoric correlation (and vice versa) (Demirtas, 2016). The tetrachoric coefficient is most often used to correlate two independent binary variables but can also be used to examine rater reliability of a single rater when two raters independently rate using a dichotomous scale (Bonett and Price, 2005).

Pearson presented this coefficient in an 1899 memoir, providing illustrations that included a horse's coat color and a person's eye color (i.e., correlating maternal grandmother eye color with granddaughter eye color with eyes of two shades, gray or lighter or dark gray or darker) (Pearson, 1900). Later researchers offered alternate approximations of the tetrachoric (e.g., Castellan, 1966; Digby, 1983).

The tetrachoric correlation has been described as "quite possibly, the single most difficult correlation coefficient to compute" (Long et al., 2009). Brown (1977) presented an algorithm for the tetrachoric correlation, and the coefficient is becoming more mainstreamed in many disciplines given today's high speed computing (Greer et al., 2003). Its use has also "been surrounded by a certain amount of mystique and a separation of researchers into two camps, believers and non-believers in underlying continuous normal variables" (Muthén and Hofacker, 1988), in other words, the extent to which a "true" dichotomy actually exists. This has led to the creation of an empirical test to determine the appropriateness of using tetrachoric correlations for binary variables (Muthén and Hofacker, 1988).

The tetrachoric correlation has also been found to be a biased estimated of the population correlation, with low expected cell frequency contributing to this bias. (Brown and Benedetti, 1977). Brown and Benedetti found that expected frequencies of 10 or more are needed to obtain reasonable standard error estimates.

Polychoric correlation

The polychoric correlation generalizes the tetrachoric correlation coefficient to more than two categories and, like the tetrachoric, has an assumption that the underlying bivariate distribution is normal. The use of polychoric correlations is common when fitting models in structural equation modeling to ordinal data (Monroe, 2018). Maximum likelihood methods have traditionally been used to estimate polychoric correlations, and when estimated in this fashion, have been found to be an unbiased estimate of the correlation between the bivariate normal variables (Olsson, 1979). More recent research using Bayesian suggests that maximum a posteriori (MAP) estimation is a better estimator of the polychoric (relative to maximum likelihood) and overcomes the shrinkage effect evident in expected a posteriori (EAP).

Research on the polychoric suggests that, for ordinal data, it outperforms the Pearson, Spearman's rhos, and Kendall's tau-b coefficients (Babakus and Ferguson, 1988) and is robust even where there is modest violation of normality (Quiroga, 1992). Additionally, MAP estimators with uniform prior (MAPU) has been found to be less sensitive to small sample size than maximum likelihood and other estimators, and for all sample sizes examined ($n = 25$ to 400) consistently outperformed maximum likelihood (Choi et al., 2011).

Additional correlations

Although an attempt has been made to address the more commonly known correlations, it is important to recognize that there are many additional correlation coefficients that have been created. Among others, these include the biweight midcorrelation and the distance correlation which are mentioned very briefly here.

The biweight midcorrelation is another robust correlation alternative to the Pearson, and is less sensitive to outliers as it is computed using the median (Langfelder and Horvath, 2012; Wilcox, 2017). In genetics, the biweight correlation has been found to outperform mutual information (MI), a generalized correlation index (Song et al., 2012).

The distance coefficient, based on Euclidean distances between sample elements (not sample moments), is analogous to the Pearson coefficient. Distance correlations are measures of dependence between random vectors but equate to zero only when there is independence in the random vectors. The distance correlation can be applied to examine dependence and is more general than the Pearson coefficient in that normality is not assumed (Székely et al., 2007).

Considerations with correlations

There are a number of statistical, as well as more theoretical, considerations that should be made when working with correlations. These include the consideration of causation in the examination of relationships, spurious correlations, restriction of range, and data considerations.

Correlation and causation

Variables that are related indicate that there is an identifiable pattern to the data. This is not meant to imply a causal relationship. Correlation coefficients allow the examination of relationships or associations but do not allow the inference of causality—albeit quite tempting to make that inference. Any attempt to draw causal inference from data which are correlated, by merely examining the correlation, is impossible and “fraught with pitfalls” (Haig, 2011). Causal inference between two variables, such as X and Y , can occur only under the following conditions: (a) X occurs prior to Y ; (b) X and Y covary; and (c) there are no confounders that occur in the relationship between X and Y . Readers interested in learning more about causation and causal inference are referred to any number of excellent choices (e.g., Morgan and Winship, 2014; Pearl et al., 2016).

Spurious correlations

A spurious correlation occurs when the correlation between two variables occurs not because one is caused by the other but rather because of a third variable. Examples of spurious correlations that have been found using actual data, with common sense indicating they are spurious, include the relationship between sour cream consumption and fatal motor cycle accidents ($r = 0.916$), the relationship between consumption of margarine and the divorce rate in Maine ($r = 0.993$), and science and technology expenditures and suicide by hanging, strangulation, and suffocation ($r = 0.86$) (Moosa, 2017). Spurious correlations are the underlying reason that cointegration analysis techniques, developed within the field of economics, were developed (Moosa, 2017). Cointegration proposes that if two integrated variables are strongly correlated, the correlation is spurious unless there is cointegration of the variables (Moosa, 2017). Moosa (2017) demonstrated that spurious correlations cannot be rejected with cointegration testing when there is a strong correlation coefficient between the underlying series, suggesting that “spurious relations cannot be revealed by testing alone and that theory, common sense, and intuition should come first”. This thought is echoed by many researchers who see the phenomena of spurious correlations particularly problematic with big data (Calude and Longo, 2017).

Restriction of range

Restriction of range occurs in correlated variables when data observed from a sample are not available across the entire range of scores for one of the correlated variables. In other words, one of the variables has very little variation. This is termed “restriction of range” as to produce a relationship between variable, there must be a certain range of values in the variables being correlated so that the correlation manifests. Recall that the computation for a correlation is based on how values deviate from the mean. If there is very little or no variation in a variable, the correlation produced using that variable will suggest little to no correlation, even if in reality the correlation is very strong. An example of restriction of range may be correlating college entrance exam scores and first semester college cumulative grade point average for gifted students. It is reasonable to suspect that the variation of college entrance exam scores for gifted students will be relatively limited. There is not enough variation in this variable to manifest into a strong relationship and the resulting correlation will be attenuated (although some research suggests range restriction may increase the correlation in the presence of outlier prone distributions such as exponential and lognormal, among others (Zimmerman and Williams, 2000)). This is an example of indirect range restriction. There is not direct truncation but rather it is produced when selection of the sample is based on another correlated variable (in this example, identification as gifted) (Sackett and Wade, 1983; Meade, 2012). Direct range restriction can also occur. In direct range restriction, the score distribution on the variable is directly truncated (Meade, 2012). For example, direct range restriction would occur in a situation where individuals complete instrument X and Y , and only those in the top scoring 10% of X are selected for the sample.

Researchers who encounter restriction of range must address it statistically. Additionally, it is important to first understand if the range restriction is direct or indirect as the steps and sequence are dependent on the type or range restriction. Hunter and colleagues have shown that using direct range restriction practices when the range restriction is indirect produces substantial negative biases in

corrected values. Steps and formulas for correcting for range restriction are available (e.g., Hunter et al., 2006), and though illustrated in the context of meta-analyses, the methods are applicable to correlations in individual studies. Thorndike's case II correction formula is commonly used in the event of direct range restriction when restriction occurs on only one variable (Thorndike, 1949) and was built upon earlier work of Pearson (Pearson, 1903). Corrections for multivariate range restriction are also available (e.g., Lawley, 1943; Johnson and Ree, 1994). More recently, researchers have proposed viewing selection as a missing data mechanism and have studied the application of missing data techniques (e.g., multiple imputation or full information maximum likelihood) (e.g., Pfaffel and Spiel, 2016; Pfaffel et al., 2016a,b; Wiberg and Sundstrom, 2009).

Data considerations

A number of data considerations have been presented previously. More general considerations, including sample size and distributional shape, will be presented here.

Sample size

As with many statistics, small sample sizes can detrimentally impact the correlation coefficient. Specifically, due to capitalizing on chance, the expected value of the squared Pearson correlation will be larger than zero when samples are small (Wishart, 1931). In the presence of other conditions sometimes experienced with correlations, sample size can be a further issue with which researchers must handle (e.g., Pfaffel and Spiel, 2016). Both the Pearson and Spearman have been found to underestimate the population correlation value for small sample sizes (de Winter et al., 2016). The underestimation in the presence of small samples (e.g., $N = 5$ and $N = 20$) is relatively minimal if the population Pearson coefficient is small or moderate (e.g., $\rho = 0.20$) but becomes more severe between 0.30 and 0.90.

The sample size needed to obtain a Fisher confidence interval for desired width with Pearson, Kendall's tau, or Spearman can be computed (Bonett and Wright, 2000), including the use of bootstrapped replicates to estimate the Pearson correlation confidence interval (Olivoto et al., 2018).

Distributional shape

When both variables being correlated are symmetrical and have the same distributional shape, the Pearson correlation between those variables can range from -1.0 to $+1.0$. However, to the extent that asymmetry and dissimilar shapes occur, the coefficient will not reach $|1|$. Researchers have also found that the Spearman and Pearson behave similarly when the correlated variables are normally distributed. However, Spearman is robust to outliers while the Pearson is quite sensitive, even in samples as large as 200 (de Winter et al., 2016). Researchers working with distributions that have kurtosis present, particularly in the presence of leptokurtic distributions, are encouraged to compute the Spearman rather than Pearson as the Pearson coefficient has been found to be more variable in the presence of leptokurtic distributions (de Winter et al., 2016).

Statistical inference is primarily concerned with making claims about unknown features of a population based on data that are randomly sampled from that population. From a frequentist perspective, these inferences or conclusions are made using probability models that are thought to have generated the data. In contrast to activities of data exploration which focus on distilling information and searching for interesting patterns using the sample data, statistical inference is focused on using the sample data to answer specific questions about the population—posed before the data are collected. Conclusions based on exploration are typically informal—inferred based on characteristics (i.e., individuals, settings, and circumstances) of the data whereas statistical inferential claims are more formal, backed by a statement of our confidence in them, and applied to a wider universe of individuals and a broader set of circumstances and settings (Garfield et al., 2008). According to Moore (2004), there are two central themes in statistical inference. The first is parameter estimation—obtaining a point estimate of a quantity of interest from the data. An example might be estimating parameters of a multiple regression model or even something as simple as estimating the mean of a continuous variable. Estimation approaches are discussed in detail in “Estimation Approaches (Least-squares, ML variants, Bayesian)”, another entry in this volume. The second theme and more germane to this entry is hypothesis testing, which consists of making probabilistic statements about the values of estimated quantities in the population. The Pearson product moment correlation (r) calculated from the sample might be used, for instance, to test the bivariate linear relation between two continuous variables in the population. Testing hypotheses often include computing confidence intervals and reporting test results using p -values. These approaches are intended to quantify uncertainty inherent when using sample data to make claims about the population as well as to evaluate the plausibility of chance as an alternative explanation to patterns in the observed data. This article discusses the components of statistical inference from a frequentist perspective including a brief introduction to probability, probability distributions, sampling distributions, sampling error, point and interval estimates and hypothesis testing.

Foundational concepts

A number of foundational concepts related to statistical inference was previously mentioned but not discussed in any detail. A brief description of each is now provided.

Population vs. sample

In general, a *population* is an entire collection of elements whose characteristics one may want to study (e.g., fifth-grade students' scores on a standardized test, length of stay in hospitals in Massachusetts, infant mortality rates in large urban cities). As suggested by these examples, a population can be of any size depending on how it is defined. It could range from a relatively small set of elements, which might be easily collected, to a large but finite number that would be impractical to collect in its entirety. Seldom are data collected from an entire population. Instead, a *random sample* from the population is drawn to infer something about the characteristics of the population. Often referred to as *parameters* denoted by Greek letters, these characteristics are numerical quantities [e.g., mean (μ), variance (σ^2), correlation (ρ)] describing the distributions of and relations among the variables of interest. These corresponding characteristics

Fig. 1 A schematic of the foundational concepts of statistical inference.

have counterparts in the sample data. These are referred to as *statistics* [e.g., mean ($\bar{x}$), variance (s^2), correlation (r)] and are estimates of the corresponding population parameters. Presuming that the sample that is gathered is truly random, and representative of the population, not only can population parameters be estimated by statistics computed from the sample data, but the accuracy of these estimates can also be assessed. These foundational concepts and their relations are summarized in **Fig. 1**.

A brief introduction to probability

The foundation of the frequentist approach to statistical inference is largely probabilistic in nature and so a brief discussion of basic probability tenets is needed to make sense of statistical results presented later. The concept of *probability* can be viewed in different ways, but most common definitions take either an analytic or frequentist perspective. The analytic perspective defines probability formally. Take for example flipping a coin and computing the probability of obtaining the outcome of a tail on a single flip. If an event (flipping of a coin and getting a tail) can occur in A ways and can fail to occur in B ways, and if all possible ways are equally likely (e.g., a tail or a head has an equal chance of happening), then the probability of its occurrence is $A/(A + B)$, and the probability of its failing to occur is $B/(A + B)$. The coin has two possible outcomes, heads or tails, and flipping a tail can only be obtained one way. Thus, the probability of obtaining a tail on a single flip of a coin using the analytic method is $Pr(tails) = 1/(1 + 1) = 0.5$.

In the previous example, it was trivial to list all of the possible outcomes of the *event*. Many real-life scenarios involving computing probabilities are not so straightforward because listing all of the possible outcomes is impractical. For instance, what is the probability of winning a game of solitaire? Here, a frequentist approach to computing probability may be more prudent. Determining the probability of flipping a tail through a frequentist approach necessitates conducting a series of trials (i.e., flips of the coin) and calculating the proportion of flips that come up tails. To keep it simple, suppose a coin was flipped 20 times and the following pattern of heads and tails was observed:

T H T H H T H T H T T H H T T T T H T T

To compute the probability of flipping a tail one simply takes the number of tails (n_T) and divides that number by the total number of independent trials ($n = 20$). The estimated probability of flipping a tail comes out to $(12/20)$ or 0.60. Of course, this value is much different from the probability computed from the analytic perspective. Our frequentist probability would be more accurate if the number of flips increased. Thus, the probability might be defined as the limit of the relative frequency of occurrence of the desired event that is approached as the number of trials increases.

$$Pr(\text{tail}) = \lim_{n \rightarrow \infty} \frac{n_T}{n}$$

That is, if the coin were flipped 100, 1000, 10,000 times or more, the probability of a tail occurring based on relative frequency would approach 0.50. Statistical inferences, as we will see, are largely based on decisions made with respect to probabilities computed from frequentist or analytical approaches.

Probability distributions

A probability distribution underlying a random variable in the population governs the probability of obtaining a specific value or the probability of a value that falls within a particular interval. This distinction is necessary because the first applies to distributions of *discrete* variables while the latter applies to distributions of *continuous* variables.

A discrete variable typically takes on one of a relatively small number of possible values (e.g., a five-point scale of socioeconomic status). A variable that can take on one of infinitely many possible values is generally treated as a continuous variable if the values represent at least an interval or ratio scale.¹ For example, consider a binomial distribution—a discrete probability distribution—to

¹The level of measurement or scale of measure refers to a classification that describes the nature of information within the numbers assigned to variables. According to [Stevens \(1946\)](#) there are four different scales of measurement: nominal, ordinal, interval, and ratio.

represent the number of heads obtained when flipping three coins. The binomial distribution deals with situations in which each of a number of independent trials results in one of two mutually exclusive outcomes. The binomial distribution is defined formally as

$$Pr(X=x) = \binom{n}{x} p^x (1-p)^{n-x}$$

where $Pr(X=x)$ is the probability of random variable X taking on a specific value x , p is the probability of a success, and n represents the number of trials. **Table 1** and **Fig. 2** show the possible outcomes of flipping three coins and observing the number of heads. For example, the probability of obtaining exactly $x=2$ heads when flipping $n=3$ coins is 0.375. For discrete distributions like the binomial distribution modeling the number of heads observed when flipping three coins, the probabilities for each discrete event can be computed and are the sum of the areas of the rectangles in **Fig. 2**. These probabilities, and thus the area of the rectangles, sum to 1. This is a characteristic of all probability distributions.

As another example, consider a continuous random variable such as weight. Weights of newborn babies in the US vary according to the normal distribution (the normal distribution is a continuous probability distribution) with approximate mean of $\mu = 7.50$ pounds and standard deviation of $\sigma = 1.25$. **Fig. 3** shows this hypothetical distribution of weights of US newborns in the population.

Here, it does not make sense to seek the probability of a particular weight, say 7.321476 lbs., which would be very small—essentially zero. However, it does make sense to determine the probability over an interval of weights, say from 6.5 lbs. to 8.5 lbs. That is, what is the probability that a randomly selected newborn from the population will weigh between 6.5 and 8.5 pounds, inclusively? This probability is denoted by $Pr(6.5 \leq x \leq 8.5)$. **Fig. 4** shows this probability as the shaded area under the normal curve and the computed probability is 0.567. While it may not be obvious, the total area under this normal distribution is 1—again a characteristic of all probability distributions. This cursory introduction to both probability and probability distributions is meant to acquaint readers to concepts that will be used later when describing frequentist procedures, such as hypothesis testing, for making statistical inferences.

Table 1 Probabilities of obtaining heads from tossing three coins using the binomial distribution.

Number of heads	Probability
$x=0$	$\binom{3}{0} 0.5^0 0.5^3 = 0.125$
$x=1$	$\binom{3}{1} 0.5^1 0.5^2 = 0.375$
$x=2$	$\binom{3}{2} 0.5^2 0.5^1 = 0.375$
$x=3$	$\binom{3}{3} 0.5^3 0.5^0 = 0.125$

Fig. 3 Normal probability distribution of US newborn babies' weights in pounds.

Fig. 4 Probability between an interval denoted by the shaded area under the curve with endpoints at 6.5 and 8.5 pounds.

Hypothesis testing

An essential, initial component of testing any hypothesis is the researcher's articulation of a research question. Most research questions in education are formulated based on an investigator's insightful observations or intuition founded in an explicit understanding of the underlying phenomenon. For example, a school district's reading specialist may conjecture that a new reading curriculum targeting bilingual children will produce higher reading comprehension scores as measured on a state-wide assessment of learning than the current curriculum (the research question). Stemming from his/her pedagogical content knowledge or expertise in bilingual education, the reading specialist may generate a research hypothesis that this new approach will impact student achievement. A research question (or research hypothesis) generally reflects a researcher's expectation of reality and should directly correspond to the statistical hypotheses to be empirically evaluated.

Translating hypotheses

A prerequisite to testing a research hypothesis is translating the question into a statistical hypothesis. A statistical hypothesis is a numerical statement regarding a hypothesized population parameter that captures the essence of the quantity articulated in

the research question. In the prior example involving a comparison between a new reading curriculum and current reading curriculum, a researcher might posit that average test scores on a standardized reading assessment for students randomly assigned to the new curriculum will be different than average test scores for students randomly assigned to the current curriculum. The corresponding statistical hypothesis operationalizes the description and formalizes the relation using appropriate parameters

$$H_0 : \mu_n - \mu_c = 0$$

$$H_1 : \mu_n - \mu_c \neq 0$$

where μ_n is mean of test scores in the population of students taking the new curriculum while μ_c is the mean of test scores in the population of students taking the current curriculum. Hypothesis testing involves comparing two hypotheses: (1) the null hypothesis and (2) the alternative hypothesis. The null hypothesis states that there is no relation (no effect) between the phenomena whose relation is under investigation. This corresponds to $H_0 : \mu_n - \mu_c = 0$ where average student test scores under the two reading curricula are the same (i.e., their difference is zero). The alternative hypothesis, as the name suggests, is the alternative to the null hypothesis stating that some kind of relation exists, $H_1 : \mu_n - \mu_c \neq 0$. Although introductory statistics courses highlight that the alternative hypothesis in this relation (e.g., one group's average test scores will be greater or less than the other group) may be directional (i.e., one-sided), the vast majority of research studies state a non-directional, two-sided, alternative hypothesis (e.g., the average test scores in the two groups are not the same). In general, for any population parameter, θ , the statistical hypothesis takes on the form

$$H_0 : \theta = K$$

$$H_1 : \theta \neq K$$

where K is any constant value—often, but not always—defined to be zero. Recall, that a parameter (a numeric quantity in the population) is unknown and a statistic computed from sample data is used as our best guess of this parameter. In the running example, $\bar{y}_n - \bar{y}_c$ would be used as a *point estimate* of $\mu_n - \mu_c$. This quantity is almost always non-zero—conforming to the alternative hypothesis. The obvious question is, “Is the observed average group difference in test scores small enough to attribute to chance variability or does the observed average group difference represent a real effect?” In other words, is the observed difference simply a result of the particular sample data we happened to obtain. If the group means in the population are actually the same, then any observed difference is attributable to *sampling error*. Answering this question will require the use of what is referred to as the statistic's sampling distribution.

Sampling distribution

A key concept of statistical inference from a frequentist perspective is the *sampling distribution* of a statistic, $\hat{\theta}$, and conveys specifically what degree of sample-to-sample variability (i.e., sampling error) can be expected by chance. In other words, the sampling distribution of a statistic (e.g., group mean difference) can be thought of as a distribution of values obtained for that statistic over repeated sampling (i.e., running the experiment, or drawing samples, an unlimited number of times). In hypothesis testing, sampling variability of a statistic, $\hat{y}_n - \hat{y}_c$ is the foundation for estimating the probability of observing a statistic equal to or more extreme than what is obtained under the true null hypothesis (i.e., no effect). To make this idea more concrete, assume we were interested in the difference in average performance on a standardized reading assessment for all second grade students assigned to receive either a new curriculum or the current curriculum (population). Our best guess of that population group mean difference ($\mu_n - \mu_c$) would be the sample group mean difference ($\bar{y}_n - \bar{y}_c$) based on a random sample of n_n and n_c observations from these two populations. If this process of drawing random samples of size n_n and n_c from the same populations were repeated many times and for each sample drawn, the mean difference between the groups was computed, the group mean differences from all the samples would vary and would form a distribution—the sampling distribution of the group mean differences. As the number of repeated samples increases, the sampling distribution is more well-defined. In the case of $\bar{y}_n - \bar{y}_c$ theoretically, the average of all possible sample group mean differences, or its expected value, $E(\bar{y}_n - \bar{y}_c)$, is equal to the population group mean difference, $\mu_n - \mu_c$. Statistics with this property, that $E(\hat{\theta}) = \theta$, are referred to as *unbiased estimators*.

Central limit theorem

The central limit theorem (CLT) provides a factual statement about the sampling distribution of the mean. Specifically, the CLT states that given a population with mean μ and variance σ^2 , the sampling distribution of the mean (i.e., the distribution of sample means) will have a mean equal to the mean of the population, μ (i.e., $\mu_{\bar{y}} = \mu$) and variance, $\sigma_{\bar{y}}^2$, equal to σ^2/n . This implies that as the sample size of the samples drawn from a population increases, the standard error of the means decreases, leading to less variability of sample means and smaller sampling error. The distribution of sample means will approach the normal distribution as n , the sample size, increases no matter what the shape of the distribution in the population is.

In the hypothetical example involving the group mean difference, testing the null hypothesis will require examining the sampling distribution of the difference between means. To be concrete, suppose $y_1 \sim N(\mu_1, \sigma_1^2)$ and $y_2 \sim N(\mu_2, \sigma_2^2)$ coming from sample sizes of n_1 and n_2 , respectively. Using the fact that the variance of the sum or difference between two independent random variables is the sum of their variances, and from the CLT that the variance of the distribution of $\bar{y}_1$ is σ^2/n_1 and the variance of the distribution of $\bar{y}_2$ is σ^2/n_2 , the variance of the difference of these two variables is the sum of their variances. Thus, the variance of the mean difference is

$$\sigma_{\bar{y}_1 - \bar{y}_2}^2 = \sigma_{\bar{y}_1}^2 + \sigma_{\bar{y}_2}^2 = \left(\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2} \right) \quad (1)$$

Coupled with the information regarding the variability of the sample mean difference in Eq. (1), the implications of the CLT are shown in Fig. 5. As the sizes of the samples drawn from the two populations increase, the variance of the sample mean difference decreases. Fig. 5 presents two sampling distributions of the mean differences, one based on $n_1 = n_2 = 10$, and the other based on $n_1 = n_2 = 50$.

The black line represents the group mean difference in the population given that the means of the two groups are equal as they would be under the null hypothesis. They are at 0 in both plots. In fact, it can be shown that $E(\bar{y}_1 - \bar{y}_2) = \mu_1 - \mu_2$. Examining the scale on the x-axis, it is clear that the group mean differences comprising the sampling distribution in the left panel are more variable around the mean value of 0. Whereas, the group mean differences in the right panel are less variable—more tightly clustered around 0. The final point to be made about this distribution concerns its shape. An important theorem in statistics states that the sum or difference of two independent normally distributed variables is itself normally distributed. Because Fig. 5 represents the difference between two sampling distributions of the mean, and because the sampling distribution of means is at least approximately normal for reasonable sample sizes, the distributions in Fig. 5 must be at least approximately normal.

Standard error

Sample-to-sample variability, or sampling error, of a sample statistic is captured by the *standard error*. In the case of the group mean difference as described previously, the standard error is the standard deviation of its sampling distribution. When samples are randomly selected from corresponding populations, the resulting distribution will be approximately normally distributed for reasonable sample sizes, n_1 and n_2 . When the standard deviations in these two populations are known, the standard error of the sampling distribution of the group mean difference is the square root of the variance in Eq. (1)

$$\sigma_{\bar{y}_1 - \bar{y}_2} = \sqrt{\left(\frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2} \right)}$$

Clearly, the standard error ($\sigma_{\bar{y}_1 - \bar{y}_2}$) depends on the size of the variability of scores in each population (i.e., σ_1^2 and σ_2^2) as well as the sample sizes n_1 and n_2 . While not a requirement, assume that the sample sizes are equal (i.e., $n_1 = n_2$). As group sample size increases, $\sigma_{\bar{y}_1 - \bar{y}_2}$ decreases to its lower limit of 0. That is, $n_1 = n_2 \rightarrow \infty$, $\sigma_{\bar{y}_1 - \bar{y}_2} \rightarrow 0$. In a similar fashion, as group sample size decreases to its lower limit of 1, $\sigma_{\bar{y}_1 - \bar{y}_2}$ increases to its upper limit of the population standard deviation, $\sqrt{(\sigma_1^2 + \sigma_2^2)}$. Generally

Fig. 5 Distributions of group mean differences from repeated sampling from populations in which the means are equal. Sample size in the left panel is $n_1 = n_2 = 10$. Sample size in the right panel is $n_1 = n_2 = 50$.

speaking, over repeated sampling, a sample statistic $\hat{\theta}$ based on a larger sample size will have less variability (i.e., less sampling error) than those based on a smaller sample size. In practice, the population standard deviations are almost never known. As we will see, a reasonable tact is to use sample standard deviations as our best guess at these unknown quantities.

Why is understanding these basic tenets of the sampling distribution of a statistic so crucial? Imagine in our running example that a sample mean difference of 0.75 was computed from the sample data (i.e., $\bar{y}_1 - \bar{y}_2 = 0.75$). Is this 0.75-point mean difference sufficiently large to justify the conclusion that the two samples were drawn from different populations as suggested by the alternative hypothesis. Or as Jones and Tukey (2000) proposed, is the difference sufficiently large for us to identify the direction of the difference in population means? Under the null hypothesis of no group mean difference, a mean difference of 0.75 does not seem so unusual based on the sampling distribution in the left panel of Fig. 5 in which the group sample size is 10, but seems quite improbable from examining the right panel in which the group sample size is 50. In addition, Fig. 5 intuitively demonstrates a number of properties of sampling distributions that will have significant implications for hypothesis testing.

Using the sampling distribution

The sampling distribution of a statistic under the presumption that the null hypothesis (H_0) is true is used to test statistical hypotheses. Because the sampling distribution is a probability distribution, this involves estimating the probability of observing a sample statistic (e.g., $\bar{y}_1 - \bar{y}_2$) equal to or more extreme than what is observed from the sample. For this probability distribution, the farther away the observed sample statistic (e.g., $\bar{y}_1 - \bar{y}_2$) is from the population parameter under the null hypothesis $H_0 : \mu_1 - \mu_2 = 0$ (i.e., out on the tails of the distribution), the more likely that the difference between $\bar{y}_1 - \bar{y}_2$ and $\mu_1 - \mu_2$ represents a real mean difference in the population and is not due to sampling variation. A sample statistic value near the population value of the sampling distribution is more indicative of sample-to-sample variation. Sample statistic values in the tails of the distribution occur less frequently in repeated sampling, and consequently, are less probable if in fact H_0 was true. In fact, a probability quantifying how likely a sample statistic is can be calculated.

Under H_0 , if this probability is judged to be smaller than a predetermined threshold probability level (denoted α), the conclusion would be that H_0 is likely not true and the alternative hypothesis is likely operating in the population. This is the basic idea behind frequentist hypothesis testing—making conclusions about population parameters using probabilistic statements regarding the likelihood of observing a sample statistic if indeed the null hypothesis in the population was true. A small probability suggests that observing such a statistic is quite unlikely. The threshold value of $\alpha = 0.05$ is conventionally used in research (although this is arbitrary), leading to the following decision rules with regard to H_0 . In general, if the probability of observing the sample statistic is smaller than the threshold α given the null hypothesis is true (i.e., $p(\hat{\theta}|H_0 \text{ is true}) \leq \alpha$), then the null hypothesis should be rejected in favor of the alternative hypothesis. The null hypothesis would be retained if $p(\hat{\theta}|H_0 \text{ is true}) > \alpha$. As Moore (2004) points out, this decision rule does not suggest that such values of the sample statistic cannot occur under the null hypothesis, H_0 . It merely states that values so extreme (i.e., those out on the tails of the sampling distribution) arise with much less frequency under H_0 and thus seem implausible if in fact the null hypothesis was true.

It is important to keep in mind that hypothesis testing is unable to address the question of whether H_0 is true given the observed statistic computed from the sample (Howell, 2011) and a chosen threshold, α . The process only involves the determination of the probability of obtaining sample statistic values equal to or more extreme than the sample result under the assumption that the null hypothesis is true. Other threshold values like $\alpha = 0.01$ or $\alpha = 0.10$ can be specified and used to make decisions when evaluating H_0 . A particular value of α is chosen by the researcher before examining the data and is based on his or her consideration of committing Type I and Type II errors. Table 2 provides a schematic of the decision making process in frequentist hypothesis testing.

The process of distinguishing between the null hypothesis and the alternative hypothesis is aided by considering two conceptual types of errors. Type I error occurs when wrongly rejecting the null hypothesis. In the running example using group mean differences one might conclude that the two groups have different means in the population when in actuality they do not. The second type of error, Type II error, occurs when the null hypothesis is wrongly retained (or not rejected). That is, there was a population mean difference between the two groups, but we wrongly said that there wasn't. The other two scenarios correspond to correct decisions regarding the state of reality in the population.

Table 2 Correct decisions and errors in hypothesis testing.

		Decisions based on sample data	
		Reject H_0	Fail to reject H_0
True state in the population	H_0 is true	Type I error (significance level) α	Correct decision (confidence level) $1 - \alpha$
	H_0 is false	Correct decision (power) $1 - \beta$	Type II error β

Test statistics and confidence intervals

Sampling distributions are critical to conducting hypothesis tests because they place the one value of the statistic computed from sample data into the broader context of all other possible values that could have been obtained over repeated sampling from the population. In practice, this allows assessing the probability of observing values more extreme than a given sample statistic under H_0 . The sampling distribution can either be derived theoretically using key concepts like the CLT or the sampling distribution can be approximated using *bootstrapping* techniques (see, *Statistical inference: Resampling approaches* in this volume). For the former, a sample statistic is typically re-expressed as a test statistic for which characteristics of the sampling distribution are known.

For example, the test statistic for evaluating a sample mean difference between two groups, $\bar{y}_1 - \bar{y}_2$ when the standard deviations, σ_1^2 and σ_2^2 in the populations are known is:

$$z_{obs} = \frac{(\bar{y}_1 - \bar{y}_2) - (\mu_1 - \mu_2)}{\sigma_{\bar{y}_1 - \bar{y}_2}}$$

This test statistic, z_{obs} , represents the distance between the sample mean difference and hypothesized population mean difference in standard deviation units, where the standard deviation is the standard error of the sampling distribution of the mean difference. A larger absolute value of z_{obs} indicates that $\bar{y}_1 - \bar{y}_2$ is further away from the hypothesized population mean under H_0 —in our running example, zero. The exact probability of observing a value of z_{obs} or larger can be obtained from tabled values found in many introductory statistics books or can be easily computed using numerous mainstream statistical software packages, even Microsoft Excel.

Applying the z -test as described above requires that the population standard deviations, σ_1^2 and σ_2^2 , be known. When these values are unknown, the standard error of the mean difference must be computed from the sample data, $s_{\bar{y}_1 - \bar{y}_2}$, where $s_{\bar{y}_1 - \bar{y}_2} = \sqrt{\left(\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}\right)}$.

The test statistic in this case is a t -statistic

$$t_{obs} = \frac{(\bar{y}_1 - \bar{y}_2) - (\mu_1 - \mu_2)}{s_{\bar{y}_1 - \bar{y}_2}}$$

which follows a t -distribution. The t -distribution is actually a family of distributions which is characterized by degrees of freedom (df). Three members of the t -distribution family are displayed in Fig. 6 with an increasing number of df ($df = 3, 10$, and ∞). Note, that as the total sample size, $N = n_1 + n_2$, increases, the t -distribution converges on the z -distribution. Beyond $df = 120$, the difference between the z - and t -distributions is negligible—the t -test becomes the z -test for all practical purposes. Test statistics other than z and t may be needed as required by a statistical analysis. For example, the χ^2 distribution is used to test whether a variance deviates from a population value (e.g., 0); or, the F distribution is used for testing two variance components. Regardless of the specific test statistic used in a particular research situation, the logic for hypothesis testing described here, remains the same.

Adjudicating whether to reject the null hypothesis can be accomplished in three different, but congruent, ways. The first method directly compares the observed sample test statistic (e.g., t_{obs} , z_{obs} , or χ_{obs}^2) against a critical value of the statistic (e.g., t_{cv} , z_{cv} , or χ_{cv}^2) as determined by the predetermined significance level, α . Similarly to computing probabilities, the critical value of a t -test statistic (i.e., t_{cv}) corresponding with a given value of α and a given df is readily available from statistical software. The second method is one discussed earlier that focuses on carrying out the hypothesis test by comparing the probability of obtaining sample statistic values more extreme than a given sample statistic, assuming the H_0 is true, against a predetermined threshold probability level (i.e., $\alpha = 0.05$). The third approach uses a $100(1 - \alpha)\%$ confidence interval of the population parameter (see upcoming section on confidence intervals). The following decision rules for testing H_0 can be established for the first two of the three approaches.

Fig. 6 T-distributions with $df = 3$ (— — —), $df = 10$ (·····), and $df = \infty$ (—).

The first decision rule compares t_{obs} against t_{cv} leading to

If $|t_{obs}| \geq |t_{cv}| \rightarrow \text{Reject } H_0$
 If $|t_{obs}| < |t_{cv}| \rightarrow \text{Fail to Reject } H_0$

This decision rule is equivalent to the previous, probability-based decision rule for testing H_0 :

If $p(t_{obs}|H_0) \leq \alpha \rightarrow \text{Reject } H_0$
 If $p(t_{obs}|H_0) > \alpha \rightarrow \text{Fail to Reject } H_0$

Hypothetical example

Returning to the running hypothetical example involving testing the mean difference in reading scores between students assigned to receive a new curriculum and those students assigned to receive the current reading curriculum. A researcher obtains test scores for $n_n = n_c = 100$ students and computes the following sample statistics: $\bar{y}_n = 75$, $\bar{y}_c = 66$, $s_n = 25$, and $s_c = 23$ of students in the two groups and is interested in testing the non-directional null hypothesis, $H_0 : \mu_n - \mu_c = 0$ at an $\alpha = 0.05$ significance level. The test statistic is

$$t_{obs} = \frac{(\bar{y}_n - \bar{y}_c) - (\mu_n - \mu_c)}{s_{\bar{y}_n - \bar{y}_c}} = \frac{(75 - 66) - 0}{3.40} = 2.65$$

where $s_{\bar{y}_n - \bar{y}_c} = \sqrt{\left(\frac{s_n^2}{n_n} + \frac{s_c^2}{n_c}\right)}$. Under the assumption of unequal population variances, $|t_{obs}| = 2.65$ exceeds the $t_{cv} [t_{(0.975, df=196.639)} = 1.972, \alpha = 0.05]$.² Thus, the null hypothesis, $H_0 : \mu_n - \mu_c = 0$, is rejected as it is very improbable ($p = 0.009$) to observe sample mean difference values equal to or greater than 9 if in fact H_0 was true.

It is highly recommended that researchers go beyond simply reporting of the results obtained from testing hypotheses to also include some measure of the size of an effect, often referred to as the *effect size*. The importance of using effect sizes in educational and psychological research was emphasized in a report by the American Psychological Association (APA) task force on statistical inference [Wilkinson et al. \(1999\)](#), which stated unequivocally that effect sizes of primary outcomes should always be presented with additional comments that place these effect sizes in a practical and theoretical context. In fact, professional journals that regularly publish research studies that use quantitative methods, currently insist on them.

In addition, some methodologists have strongly argued that statistical significance is the least interesting thing about the results and should also be described in terms of its magnitude. An appropriate effect size for our running example of the mean difference in reading scores in two experimental conditions would be a standardized mean difference as measured by Cohen's d or Hedge's g . The type of effect size would convert the actual mean difference of 9 points onto a standard deviation scale. Colloquially, a statistically significant result suggests that the new reading curriculum affects students, but an effect size provides information on how much does it affect them. For our running example, Cohen's d would be calculated as

$$d = \frac{(\bar{y}_n - \bar{y}_c)}{s_{pooled}} = \frac{(75 - 66)}{24.021} = 0.375$$

The value 0.375 can be interpreted as the standardized mean difference in reading scores between the two groups. This might be categorized as a small-to medium-size effect ([Cohen, 1988, 1994; Kelley, 2007](#)).

Confidence intervals

The method of testing a hypothesis described above is a point-estimate approach that results in a dichotomous decision (i.e., reject or fail to reject H_0). An interval estimation approach can also be used to test a statistical hypothesis and provides the additional benefit of producing a range of values within which a population parameter is likely to reside. That is, interval estimates are attempts to set limits that have a high probability of encompassing the population parameter. From a frequentist perspective, these intervals are called *confidence intervals* (CI). In general, a CI for an unknown parameter is a recipe that, in repeated samples, yields intervals that contain the true parameter with a prespecified probability, the confidence level, $1 - \alpha$. For instance, a 95% CI would be interpreted to mean that 95% of similarly constructed intervals will contain the population parameter while 5% of them will not. This concept is illustrated in [Fig. 7](#) for a hypothetical situation where 20 random samples were drawn from two populations and the sample mean difference was subsequently computed and a 95% confidence interval was constructed from each sample. Out of the 20 CIs for $\mu_1 - \mu_2$, 19 (or 95%) contained the population parameter (i.e., true mean difference), and 1 did not.

²If equal variances are assumed in the two groups, then the formula for the standard error reduces to a pooled estimate, $s_{\bar{y}_n - \bar{y}_c} = s_{pooled} \sqrt{(1/n_n) + (1/n_c)}$,

where $s_{pooled} = \sqrt{\frac{[(n_n - 1)s_n^2 + (n_c - 1)s_c^2]}{(n_n + n_c - 2)}}$.

Fig. 7 Twenty 95% confidence intervals for the population mean difference, $\mu_1 - \mu_2$.

It is very tempting to say that the probability is 0.95 that the interval includes the population mean difference. Confidence intervals are random variables and will vary from one study to the next while the population parameter is fixed. A specific interval—once calculated from the sample data—is no longer a random variable and therefore does not have a probability associated with it.

A CI can be constructed for a population parameter, θ , using $\hat{\theta}$ estimated from the sample. For a given significance level, α ,

$$100 \cdot (1 - \alpha)\% \text{ CI} = \hat{\theta} \pm t_{\left(1-\frac{\alpha}{2}\right)} \cdot SE_{\hat{\theta}}$$

This is the conventional definition of a symmetric CI under a true H_0 , where $t_{\left(1-\frac{\alpha}{2}\right)}$ is the appropriate test statistic (e.g., z , t) value at the $100 \times \left(1 - \frac{\alpha}{2}\right)$ percentile point of its distribution, and $SE_{\hat{\theta}}$ is the estimated standard error of the sampling distribution. Upper and lower limits of the CI can be obtained by adding and subtracting the quantity $t_{\left(1-\frac{\alpha}{2}\right)} \cdot SE_{\hat{\theta}}$ resulting in the CI:

$\left(\hat{\theta} - T_{\left(1-\frac{\alpha}{2}\right)} \cdot SE_{\hat{\theta}}, \hat{\theta} + T_{\left(1-\frac{\alpha}{2}\right)} \cdot SE_{\hat{\theta}} \right)$. This has a $(1 - \alpha)$ probability of containing the unknown population parameter, θ . As was mentioned previously, using a CI is the third method of adjudicating a hypothesis test. Given H_0 is true, the hypothesized population parameter value falling outside a CI constructed in this manner leads to the rejection of H_0 . Conversely, a CI containing the parameter value would lead to the decision of failing to reject H_0 .

Returning once again to our hypothetical running example about evaluating a new reading curriculum, where $\bar{y}_n - \bar{y}_c = 9$, $s_{\bar{y}_n - \bar{y}_c} = 3.40$, and t critical value is $t_{(0.975, df=196.639)} = 1.972$ at the $\alpha = 0.05$ level. The 95% CI for $\mu_n - \mu_c$ would be (2.30, 15.71) with the lower limit computed as $9 - (1.972 \times 3.4)$ and the upper limit computed as $9 + (1.972 \times 3.4)$. As this CI does not contain 0, the value under the null hypothesis, then H_0 would be rejected (just as it was using the other two decision rules).

Discussion

Indisputably, modern scientific thinking has been greatly enhanced by thoughtful statistical reasoning. Part of that reasoning is directed at making inferences about a population based on sample data. From a frequentist viewpoint, statistical inference involves many interrelated activities. This non-exhaustive set includes, (1) choosing a statistic that best represents the phenomena to be investigated, (2) obtaining a random sample from a target population, (3) estimating the statistic using sample data, and (4) using the null hypothesis significance testing (NHST) paradigm and confidence intervals to make probabilistic statements about the true values of corresponding parameters in the population. This paradigm has dominated the educational, social and behavioral science research landscape over the past 90+ years since the seminal works by Fisher (1925) and Neyman and Pearson (1928). Perezgonzalez (2015) provides an informative account of the chronology of hypothesis testing up through the beginning of the 21st century

and Lehmann (1993) provides a readable commentary regarding the similarities and differences between Fisher and Neyman and Pearson's perspectives on hypothesis testing. Yet, the NHST paradigm is not without its critics, which have led to alternative statistical inferential paradigms.

In 2019, the American Statistical Association (ASA) published a special issue related to statistical inference in the 21st century. In the leading article, Wasserstein et al. (2019) wrote on behalf of the ASA stating.

The ASA statement on p -values and statistical significance stopped just short of recommending that declarations of “statistical significance” be abandoned. We take that step here. We conclude, based on our review of the articles in this special issue and the broader literature, that it is time to stop using the term “statistically significant” entirely. Nor should variants such as “significantly different”, $p < 0.05$, and “nonsignificant” survive, whether expressed in words, by asterisks in a table, or in some other way. (p. 2).

The sentiments (or mandates) embodied in this quote and throughout this special issue in the American Statistician should give each applied scientist and quantitative methodologist pause. While the NHST paradigm is unlikely to disappear anytime soon, there are a few take-away messages that are worth highlighting with these criticisms in mind. Be open, thoughtful, and modest when interpreting statistical results and drawing inferences. An inferential statement provides only an approximation to the truth and therefore, should be accompanied and contextualized by some measure of uncertainty associated with it. As Wasserstein later asserted, “... small p -values are like a right-swipe in Tinder. It means you have an interest. It doesn't mean you're ready to book the wedding venue.”

Two alternatives to the NHST paradigm already exist and worth mentioning here. The first is statistical inference from a Bayesian point-of-view. Bayesian inference (see *Statistical inference: Bayesian approaches*, an entry in this volume) is an approach to statistical inference in which Bayes' theorem is used to update the *probability for a hypothesis* as more evidence or information about model parameters and additional data becomes available. The second inferential paradigm is model-based (see, e.g., Anderson, 2008; Burnham and Anderson, 2002) using information criteria such as Akaike's information criterion (AIC; Akaike, 1974) or the Bayesian information criterion (BIC; Schwarz, 1978). This paradigm focuses on the principle of multiple working hypotheses that encourages researchers to think hard to identify several plausible scientifically-justifiable hypotheses—where inferences are conditional on this set of alternatives. Each scientific hypothesis corresponds to a statistical model thought to have generated the data whose parameters capture some interesting facet of the phenomenon. The researcher provides several pieces of *evidence* arguing why one should prefer a particular hypothesis over another—with the data as the final arbiter. Both Bayesian and informatic-theoretic approaches are relatively new to the social and behavioral sciences and therefore are not yet well established in the applied literature. It is unclear whether one paradigm for statistical inference is better, or more effective, than another. However, one thing is certain. The landscape for making statistical inferences in a frequentist framework is changing and will continue to do so.

Overview

Resampling in statistics generally refers to creating new data sets from a random sample $Y = (Y_1, \dots, Y_n)^T$ to help with inference based on estimators or test statistics, or any quantity that is simply a function of Y like the sample mean or sample median or the t statistic. Actually, we might be interested in $t = \sqrt{n}(\bar{Y} - \mu)/s_{n-1}$ as a test statistic with $\mu = \mu_0$ a known constant or as a *pivotal quantity* with unknown μ used to get confidence intervals. Denote any of these random quantities generally by $T(Y)$. The focus of this entry is on the bootstrap, the jackknife, and permutation tests. All three methods are used to estimate certain aspects of the sampling distribution of $T(Y)$ such as the variance or percentiles of $T(Y)$. Other resampling methods (not discussed here) include cross-validation, random subsampling, and balanced repeated replications—see [Efron \(1982\)](#) and [Efron and Tibshirani \(1993\)](#) for discussion of these.

It is very easy to be confused by the two levels of distributions in play here. The population that Y is sampled from may have a mean μ or a 95th percentile $\eta_{0.95}$, but those are not the direct focus of the resampling methods. To be clear, let us consider the simplest situation where $Y_1, \dots, Y_n$ are independent and identically distributed from a population with mean μ and variance σ^2 . In this case, we know that the sample mean $\bar{Y}$ estimates μ unbiasedly, $E(\bar{Y}) = \mu$, and its variance is $\text{Var}(\bar{Y}) = \sigma^2/n$. These latter calculations are based on the sampling distribution of $\bar{Y}$, which is inherited from the distribution of the sample. In fact, we know from the Central Limit Theorem that the sampling distribution of $\sqrt{n}(\bar{Y} - \mu)/\sigma$ converges to a standard normal distribution in large samples. In this simple case, the nonparametric bootstrap estimate of the variance of $\bar{Y}$ is s_n^2/n , where $s_n^2 = n^{-1} \sum_{i=1}^n (Y_i - \bar{Y})^2$ is

the “ n ” version of the sample variance. The jackknife estimator is s_{n-1}^2/n , where $s_{n-1}^2 = (n-1)^{-1} \sum_{i=1}^n (Y_i - \bar{Y})^2$ is the “ $n-1$ ” version of the sample variance.

Now, I give a brief introduction to our three resampling methods.

1. The bootstrap introduced by [Efron \(1979\)](#) is the simplest of the resampling methods and is based on drawing random samples from the original sample, mimicking the original sampling plan as closely as possible. Its scope of application is very wide and can be used for bias and variance estimation, confidence interval construction, hypothesis testing, and for other less well-known inferential goals.
2. The jackknife was introduced by [Quenouille \(1949, 1956\)](#) as a general method to remove bias from estimators, but [Tukey \(1958\)](#) noticed it also led to a method for estimating variances, and that quickly became its main use. Resampling with the

jackknife is simply creating new samples by dropping out each data point one by one, thereby creating n data sets of size $n-1$. The $T(Y)$ of interest is calculated on each of the “delete-1” data sets, and the jackknife variance estimate is based on the sample variance of these n T s.

3. In the early 1930s, R. A. Fisher discovered a very general method of testing hypotheses based on permuting the data in ways that do not change its joint distribution under the null hypothesis. These permutations (data modifications) are the resamples. A test statistic calculated for each resample allows construction of a null distribution for the test statistic. This *permutation* method does not require standard parametric assumptions such as normality of the data. It does require, however, certain invariance properties under the null hypothesis that restricts application to fairly simple designs. But in such situations, the method results in exact tests with level α under very weak distributional assumptions. Moreover, the method is *statistic-inclusive* in the sense that any test statistic can be used and inherits the level- α property, although some test statistics are much more powerful than others. Tests based on this method are called permutation tests (or randomization tests).

Fundamentals

Here we discuss very briefly the components required to understand the bootstrap: random sampling from populations and Monte Carlo simulation.

Statistical populations

To understand our three resampling methods, we need to go back to the basics underlying statistical inference about a population. A statistical population is simply a set of numbers such as

$$\{x_1, x_2, \dots, x_N\}, \quad \text{for example } \{10, 10, 20, 20, 20, 30, 40, 50\}. \quad (1)$$

If there are replications like the two 10s and three 20s above with $N = 8$, we would just give the unique values $\{10, 20, 30, 40, 50\}$ and the relative frequencies $p_1 = 2/8$, $p_2 = 3/8$, $p_3 = 1/8$, $p_4 = 1/8$, and $p_5 = 1/8$. These relative frequencies may be thought of as probabilities of randomly drawing one member from the population. Taken together, the possible values and the relative frequencies define a population and are also called the *distribution* of the possible values. Here we might be interested in estimating the population mean

$$\mu = (2/8) * 10 + (3/8) * 20 + (1/8) * 30 + (1/8) * 40 + (1/8) * 50 = 25.$$

Often, we use statistical models, also called parametric models, to describe populations. The two best-known models for discrete populations are the *binomial distribution* and the *Poisson distribution*. The best-known continuous data models are the *normal distribution* and the *exponential distribution*.

The goal of statistical inference is to estimate population parameters like the mean μ or variance σ^2 with some notion of estimator variability, or form a confidence interval that gives an interval of plausible values for the population parameter, or carry out a hypothesis test of a specified null value θ_0 . In order to carry out statistical inference, we must obtain a random sample from the population of interest.

Random samples

Suppose that we get a randomly selected member of a population, Y_1 . The distribution of that Y_1 is the same as the population distribution, and it has the same mean and variance and other characteristics of the population. However, to carry out statistical inference, we need a bunch of similarly randomly selected members of the population denoted by $Y_1, \dots, Y_n$ and called a random sample. Characteristics of the sample like the sample mean $\bar{Y}$ and sample variance s_{n-1}^2 are used to estimate the analog population characteristics. (There are many other types of random samples, like stratified or cluster survey sampling, but for simplicity we stick with the simplest form.)

Monte Carlo simulation

This last “fundamental” is crucial for understanding the standard way to compute the bootstrap. The field of statistics has a long history of studying parameter estimators and associated confidence intervals and hypothesis tests. However, statistical theory has trouble dealing with the sampling distributions of estimators that are more complex than $\bar{Y}$ and s_{n-1}^2 . So, how can we evaluate whether new procedures in complicated situations are useful? The answer is that we run computer experiments to evaluate the new procedures, and we do something very similar with the bootstrap. On a computer, it is very easy to generate N independent

random samples, each of size n , from a population like the Poisson or normal. Here is what these N samples look like (Y is a column vector, hence the use of the superscript T for transpose).

$$\begin{aligned} Y_1 &= (Y_{1,1}, \dots, Y_{1,n})^T \\ Y_2 &= (Y_{2,1}, \dots, Y_{2,n})^T \\ &\dots \\ &\dots \\ &\dots \\ Y_N &= (Y_{N,1}, \dots, Y_{N,n})^T \end{aligned} \quad (2)$$

Let $T(Y)$ be any sample statistic of interest, for example, a parameter estimate or a test statistic. Compute $T()$ for each of the above N samples resulting in $T(Y_1), \dots, T(Y_N)$. This is not a random sample from the original population, but rather a random sample from the sampling distribution of $T()$ when samples of size n are generated from the original population. We can use this sample to estimate anything regarding the sampling distribution of $T()$. For example, we can estimate the mean using $\bar{T} = N^{-1} \sum_{i=1}^N T(Y_i)$

and the variance using $s_T^2 = (N-1)^{-1} \sum_{i=1}^N (T(Y_i) - \bar{T})^2$. The mean would tell us about the bias of an estimator. The variance could be compared with the variance of competing estimators. We could evaluate the rejection rate of test statistics under the null (Type I error rates) and under alternatives (power = 1 - Type II error rates). Keep in mind, we can do all this because we are generating the data from a known distribution. When using the bootstrap, we do not know the true population that the sample comes from.

The bootstrap

Suppose that we have a sample $Y = (Y_1, \dots, Y_n)^T$ from an unknown population and an estimator $\hat{\theta}(Y)$ for some population parameter θ . How can we estimate the variance of $\hat{\theta}(Y)$ using the nonparametric bootstrap method? We simply mimic the Monte Carlo method of the previous section, but instead of generating the samples from the true population, we treat the sample itself as a population and draw B samples from it, resulting in

$$\begin{aligned} Y_1^* &= (Y_{1,1}, \dots, Y_{1,n})^T \\ Y_2^* &= (Y_{2,1}, \dots, Y_{2,n})^T \\ &\dots \\ &\dots \\ &\dots \\ Y_B^* &= (Y_{B,1}, \dots, Y_{B,n})^T \end{aligned} \quad (3)$$

We then calculate $\hat{\theta}$ for each Y_i^* resulting in a random sample $\hat{\theta}_i^* = \hat{\theta}(Y_i^*), \dots, i = 1, \dots, B$. Note that these are conditionally independent, holding the original sample $Y_1, \dots, Y_n$ fixed. The first thing of interest is to estimate the variance of $\hat{\theta}(Y)$ by the sample variance of the $\hat{\theta}_i^*$,

$$\hat{V}_{\text{Boot}} = s_{B-1}^2 = \frac{1}{B-1} \sum_{i=1}^B (\hat{\theta}_i^* - \bar{\hat{\theta}}^*)^2.$$

Note that we have just described the *nonparametric bootstrap*; later we discuss the *parametric bootstrap* approach that draws samples exactly like the Monte Carlo method of the previous section (but using estimated parameters).

For illustration, consider the following $n = 13$ college course evaluations ("How effective was the instructor?") for the same class and instructor over multiple semesters, ordered from smallest to largest:

3.60 3.85 4.02 4.03 4.09 4.14 4.22 4.44 4.52 4.52 4.55 4.62 4.67

The sample median is the middle value, 4.22. Let us use $B = 10$ resample data sets to estimate the variance of the sample median—without the bootstrap, this is a non-trivial task. To draw a bootstrap resample, just randomly select $n = 13$ values with replacement from the above data set. Then repeat $B - 1$ more times. Here are the first three resamples, each sorted from smallest to largest:

3.60 3.85 4.02 4.02 4.09 4.14 4.22 4.44 4.52 4.52 4.52 4.55 4.67
3.60 3.60 4.02 4.02 4.14 4.14 4.22 4.44 4.52 4.62 4.62 4.67 4.67
3.60 3.85 3.85 3.85 4.03 4.03 4.44 4.44 4.52 4.52 4.55 4.62 4.67

Note that in the first resample, 4.02 shows up twice, and 4.52 shows up three times. These repetitions are the result of using sampling with replacement (Note that using sampling *without replacement* would give the original sample every time). The medians of these three resamples are 4.22, 4.22, and 4.44, respectively. The full set of $B = 10$ medians is

4.22 4.22 4.44 4.22 4.09 4.52 4.44 4.44 4.03 4.09.

The sample variance of these 10 medians is 0.0390. If repeat this process with $B = 10$ three more times, we get bootstrap estimates of variance $\hat{V}_{\text{boot}}$ of the median = 0.0390, 0.0354, 0.0347, and 0.0370. Why are these four bootstrap estimates different? It is because each estimate is based only on samples of size $B = 10$. We call this the variability due to Monte Carlo sampling. Raising B to $B = 1000$, we get bootstrap estimates 0.0304, 0.0294, 0.0301, 0.0301, with only differences in the 3rd decimal place. Letting B get very large, essentially gives the “official” bootstrap variance estimate 0.030 with no Monte Carlo variability.

However, let us consider a hypothetical second sample of $n = 13$ course evaluations from the same population. The sample median would of course be different from 4.22 of the original sample, but the “official” bootstrap variance estimate of the median, with no Monte Carlo variability, is likely to be much different than the 0.030 of the first sample. That difference comes from the sample-to-sample variability of the “official” bootstrap variance estimate. Thus, when using $B = 10$ or even $B = 1000$ to estimate the “official” bootstrap variance estimate, there are two sources of variation: (i) the Monte Carlo variation that can be driven to zero by choosing B larger and larger, and (ii) the sample-to-sample variation that cannot be made smaller unless we can increase the sample size n of the original sample.

For variance estimation, the typical recommendation is to use between $B = 100$ and $B = 1000$ resamples because the sample-to-sample variance of the “official” variance estimate (based on conceptually repeating the original collection of $n = 13$ evaluations) is much higher than the Monte Carlo variability in the variance estimates due to using $B < \infty$.

Bootstrap confidence intervals

Since the sample median has an approximate normal distribution in large samples, we might use $4.22 \pm 1.96 * \sqrt{0.030}$ yielding the approximate 95% interval (3.88, 4.56). Efron and Tibshirani (1993, p. 154) call this the *standard confidence interval*. Efron’s (1981) first bootstrap interval method was merely to take the 2.5th and 97.5th percentiles of the bootstrap sample $\hat{\theta}_1^*, \dots, \hat{\theta}_B^*$, and he called it the *bootstrap percentile interval*. Efron generally recommends B to be larger for confidence intervals than for variance estimation, perhaps 2000 or more. Using $B = 2000$ here, we obtain (4.02, 4.52). Efron (1981, 1987) also proposed more advanced bootstrap intervals call the bias-corrected (BC) and BC_a (bias-corrected accelerated), but for this example they are essentially the same as the percentile method. These more complex intervals have theoretically better convergence properties but often do not improve much over the percentile method in small samples.

The proportion of A’s received in the 13 classes above was also available. Here are both variables in the original order. A plot of the data is in Fig. 1

class	1	2	3	4	5	6	7	8	9	10	11	12	13
Eval	4.02	4.14	4.09	3.85	4.03	3.60	4.22	4.52	4.44	4.67	4.62	4.52	4.55
A’s	0.22	0.34	0.42	0.29	0.26	0.30	0.38	0.52	0.44	0.45	0.56	0.74	0.32

The Pearson correlation coefficient estimate is $r_p = 0.66$, and the Spearman rank correlation estimate is $r_s = 0.76$. Using $B = 10,000$, the bootstrap estimate of variance for r_p is 0.013 and for r_s it is 0.022. For observing Monte Carlo variation, the

Fig. 1 Class average evaluations versus proportion of A’s in each course.

bootstrap estimate of variance for r_p using five independent runs of $B = 100$ was 0.012, 0.017, 0.013, 0.014, and 0.010. To completely avoid that variation, we used $B = 10,000$.

The associated standard 95% confidence interval for ρ_p is $0.66 \pm 1.96 * \sqrt{0.013}$, or (0.44, 0.88). For the Spearman correlation ρ_s , it is $0.76 \pm 1.96 * \sqrt{0.0215}$, or (0.47, 1.00), where we truncated at 1.00. The bootstrap percentile intervals are (0.44, 0.88) and (0.36, 0.93), respectively. Perhaps the percentile interval for ρ_s is shifted to the left of (0.47, 1.00) because the estimate 0.76 is somewhat close to its upper bound of 1.00.

Bootstrap hypothesis testing

Suppose that we have two independent samples $X_1, \dots, X_m$ and $Y_1, \dots, Y_n$ and would like to test the null hypothesis of equal means $H_0 : \mu_X = \mu_Y$. For simplicity, let us use the pooled t statistic, $t_p = (\bar{X} - \bar{Y}) / \sqrt{s_p^2(1/m + 1/n)}$, where s_p^2 is the usual pooled variance estimate. Following the above methods, we might draw B sets of independent bootstrap samples from the X and Y samples, and calculate t_p for each one. Unfortunately, this would not be appropriate for hypothesis testing because we need to estimate the sampling distribution of t_p under the null hypothesis, that is with equal means. But here, the bootstrap sampling would be from populations with means $\bar{X}$ and $\bar{Y}$, respectively. One way to resample and force equal means is to get draw bootstrap samples with replacement from $(X_1, \dots, X_m, Y_1, \dots, Y_n)$. This approach actually forces both resamples to be drawn from the exact same population (and is similar to the permutation approach of the next section). An alternative that allows for different “population” distributions (and different variances) but equal means is to sample X^* with replacement from $(X_1 - \bar{X}, \dots, X_m - \bar{X})$ and Y^* from $(Y_1 - \bar{Y}, \dots, Y_n - \bar{Y})$. The key idea when bootstrap sampling for hypothesis testing is that the null hypothesis must be preserved (or forced) in the bootstrap pseudo-populations.

Parametric bootstrap

In some situations, one might be comfortable assuming that the sample $Y = (Y_1, \dots, Y_n)^T$ are independent and identically distributed from a parametric family like the exponential family having density $f(y; \sigma) = (1/\sigma)\exp(-y/\sigma)$, $y > 0, \sigma > 0$. The natural estimator of σ is the sample mean $\bar{Y}$, and the estimated density is then $f(y; \bar{Y})$. The parametric bootstrap draws resamples from this estimated density instead of treating the sample as a population and drawing resamples from it. This method is exactly like the Monte Carlo method of the [Fundamentals](#) section except that here σ is replaced by $\bar{Y}$. The main downside of the parametric bootstrap is that it depends on the parametric assumption being correct, which is the reason that the nonparametric bootstrap is dominant in practice. The following example, however, is a perfect place for the parametric bootstrap leading to an exact hypothesis test (up to Monte Carlo approximation).

Table 11.1 of [Boos and Stefanski \(2013, p. 414\)](#) reports 35 yearly maximum flow rates (gallons per second) at one river gauging station in North Carolina. For subsequent analysis it was important to confirm that the maxima actually follow an extreme value (Gumbel) distribution with cumulative distribution function (CDF) $F(x; \mu, \sigma) = F_0((x - \mu)/\sigma)$, where $F_0(y) = \exp\{-\exp(-y)\}$. The left panel of [Fig. 2](#) gives a histogram of the 35 sample values overlaid with the estimated extreme value density $(1/\hat{\sigma})f_0((x - \hat{\mu})/\hat{\sigma})$, where $(\hat{\mu}, \hat{\sigma})$ are the maximum likelihood estimates. A formal assessment is given by the Anderson-Darling test statistic

$$AD = -n - \frac{1}{n} \sum_{i=1}^n (2i-1) \left[\log \left\{ F \left(Y_{(i)}; \hat{\theta} \right) \right\} + \log \left\{ 1 - F \left(Y_{(n+1-i)}; \hat{\theta} \right) \right\} \right],$$

Fig. 2 Left panel: histogram of 35 maxima of river flow with estimated extreme value density. Right panel: histogram of $B = 1000$ Anderson-Darling bootstrap test statistics for the extreme value distribution. $T_0 = 0.178$ for original data is marked with vertical line.

where $Y_{(1)} \leq \dots \leq Y_{(n)}$ are the sample ordered values. Here the parametric bootstrap can be used to estimate the sampling distribution of AD when the sample is drawn from an extreme value distribution (the null hypothesis). It turns out that this sampling distribution is the same for any set of parameter values; so we just.

1. Generate B samples of size n from the extreme value distribution with $\mu = 0$ and $\sigma = 1$.
2. Find the maximum likelihood estimators $\hat{\mu}^*$ and $\hat{\sigma}^*$ for each bootstrap sample.
3. Compute AD above for each bootstrap sample and using $\hat{\mu}^*$ and $\hat{\sigma}^*$. Call these $AD_1^*, \dots, AD_B^*$.
4. The bootstrap estimated p -value is $\hat{p}_{\text{Boot}} = [\text{Number of } AD_i^* \geq AD_0]/B$, where AD_0 is the test statistic computed on the original sample.

Carrying this out for the max flow rates where $n = 35$, $AD_0 = 0.178$, and using $B = 1000$ leads to $\hat{p}_{\text{Boot}} = 0.93$ with standard error 0.01. The right panel of [Fig. 2](#) gives a histogram of the AD_i^* along with a vertical line at the observed value $AD_0 = 0.178$. We could also carry this out this approach to test goodness-of-fit for any location-scale family by merely replacing the base CDF F_0 by any other F_0 of interest. For example, letting F_0 be the standard normal leads to an estimated p -value against normality $\hat{p}_{\text{Boot}} = 0.20$. That seems a little unusual because the data are clearly skewed, but the AD statistic is an omnibus test and may not fully catch the skewness. A more focused test is to use the sample third moment skewness measure $m_3/m_2^{1.5}$, where $m_k = n^{-1} \sum_{i=1}^n (Y_i - \bar{Y})^k$. The skewness estimate here is 0.96, but the normal distribution population skewness is 0. Sampling again from the standard normal, the two-sided parametric bootstrap p -value is $\hat{p}_{\text{Boot}} = 0.017$ with standard error 0.001 using $B = 10,000$, certainly evidence against a normal distribution.

When does the nonparametric bootstrap “work”?

First, for the bootstrap to “work,” we mean that estimated bootstrap distribution of a sample statistic T has the same distribution in large samples as the large sample limit of the true sampling distribution of T . Basically, this happens when T has approximately a normal (or χ^2) distribution in large samples. Some typical theorems are given in [Shao and Tu \(1995, Ch. 3\)](#). But it is much more enlightening to look at examples where the nonparametric bootstrap does not work. A counterexample from [Bickel and Freedman \(1981\)](#) is for a sample drawn from a uniform $(0, \theta)$ distribution with density $f(y; \theta) = 1/\theta$ if $y \in (0, \theta)$, and 0 otherwise. The maximum likelihood estimator of θ is the sample maximum, say $Y_{(n)}$ where $Y_{(1)} \leq Y_{(2)} \leq \dots \leq Y_{(n)}$ are the ordered sample values. The pivotal quantity $T = n(\theta - Y_{(n)})/\theta$ has a limiting standard exponential distribution in large samples. However, the analog bootstrap quantity is $T^* = n(Y_{(n)} - Y_{(n)}^*)/Y_{(n)}$, where $Y_1^* \leq Y_{(2)}^* \leq \dots \leq Y_{(n)}^*$ is an ordered nonparametric resample (Note that $Y_{(n)}$ plays the role of θ in the bootstrap pseudo-population). It turns out that T^* does not converge in large samples, so the nonparametric bootstrap fails. However, the parametric bootstrap based on sampling from $f(y; \bar{Y}) = (1/\bar{Y})\exp(-y/\bar{Y})$ has the correct limiting distribution. An alternative nonparametric bootstrap that resamples with sample size $m < n$ and having special constraints on the growth rate of m with n leads to the correct convergence of T^* (see, e.g., [Swanepoel, 1986](#)). This “ m out of n ” nonparametric bootstrap can be used in other *nonregular* cases, but it is not as appealing because of the choice of m .

Bootstrap resources

Some of the early important papers in the statistics literature are [Efron \(1979, 1981\)](#), [Bickel and Freedman \(1981\)](#), [Efron \(1982, 1987\)](#), [Hall \(1988\)](#). Important theoretical books are [Hall \(1992\)](#), [Shao and Tu \(1995\)](#), and [Davison and Hinkley \(1997\)](#). For general audiences, the best single source is the book by [Efron and Tibshirani \(1993\)](#). Expository articles include [Hinkley \(1988\)](#), [Efron \(2003\)](#), [Boos \(2003\)](#), [Boos and Stefanski \(2010, 2013, Ch. 11\)](#), and [Hesterberg \(2015\)](#). The two main R packages for bootstrap calculations are `bootstrap` (v2019.6, [Tibshirani et al., 2019](#)) and `boot` (v1.3–26, [Canty and Ripley, 2021](#)); `MonteCarlo.se` ([Boos et al., 2019](#)) has simple R functions for getting bootstrap standard errors in Monte Carlo studies.

The jackknife

The jackknife method preceded the bootstrap by 30 years ([Quenouille, 1949, 1956](#); [Tukey, 1958](#)), but has a much narrower focus, basically bias estimation/correction and variance estimation. To start, consider a random sample $Y = (Y_1, \dots, Y_n)^T$ and an estimator $\hat{\theta}(Y)$ of a population parameter θ . Then let $\hat{\theta}_{[i]}$ denote the “leave-1-out” estimator obtaining by computing $\hat{\theta}$ with Y_i deleted from the sample. Denote the average of these “leave-1-out” estimators by $\bar{\theta}_1 = n^{-1} \sum_{i=1}^n \hat{\theta}_{[i]}$ and define the pseudo-values by

$$\hat{\theta}_{ps,i} = n\hat{\theta} - (n-1)\hat{\theta}_{[i]}. \quad (4)$$

The average of these pseudo-values is the bias-adjusted jackknife estimator

$$\hat{\theta}_J = \frac{1}{n} \sum_{i=1}^n \hat{\theta}_{ps,i}.$$

The jackknife variance estimator for $\hat{\theta}$ can be defined in terms of the sample variances of the leave-1-out $\hat{\theta}_{[i]}$ or of the pseudo-values Eq. (4) as follows,

$$\hat{V}_J = \frac{(n-1)^2}{n} \frac{1}{n-1} \sum_{i=1}^n (\hat{\theta}_{[i]} - \bar{\theta}_1)^2 = \frac{1}{n} \frac{1}{n-1} \sum_{i=1}^n (\hat{\theta}_{ps,i} - \hat{\theta}_J)^2. \quad (5)$$

The latter form shows that we treat the pseudo-observations somewhat like a Monte Carlo random sample of independent $\hat{\theta}'$ s.

Examples

The simplest example is the sample mean $\hat{\theta} = \bar{Y}$. In this case, the leave-1-out estimators are $\hat{\theta}_{[i]} = (n\bar{Y} - Y_i)/(n-1)$, and the pseudo-values are $n\bar{Y} - (n\bar{Y} - Y_i) = Y_i$, the observations themselves. Thus $\hat{V}_J = s_{n-1}^2/n$. Recall that the parallel bootstrap variance estimator is $\hat{V}_{\text{Boot}} = s_n^2/n$, which uses the biased “n” version of the sample variance.

The simplest nonlinear estimator is the sample variance $\hat{\theta} = s_n^2 = n^{-1} \sum_{i=1}^n (Y_i - \bar{Y})^2$, which estimates the population variance $\sigma^2 = E(Y_1 - \mu)^2$. The leave-1-out estimators are a bit ugly, but the pseudo-values are

$$\hat{\theta}_{ps,i} = \left(\frac{n}{n-1}\right) (Y_i - \bar{Y})^2, \quad i = 1, \dots, n.$$

Taking the average of the pseudo-values, we obtain

$$\hat{\theta}_J = \frac{1}{n} \sum_{i=1}^n \hat{\theta}_{ps,i} = \frac{1}{n-1} \sum_{i=1}^n (Y_i - \bar{Y})^2,$$

the usual unbiased version of the sample variance. This illustrates how $\hat{\theta}_J$ is less biased than $\hat{\theta}$ where in this case $E_F\{\hat{\theta}\} = \{(n-1)/n\}\sigma^2$. Note also that

$$\hat{\theta}_{ps,i} - \hat{\theta}_J = \left(\frac{n}{n-1}\right) \left\{ (Y_i - \bar{Y})^2 - s_n^2 \right\}.$$

Finally, using the $(n-1)$ version sample variance of $\hat{\theta}_{ps,i}$ divided by n , we get

$$\hat{V}_J = \frac{1}{n(n-1)} \sum_{i=1}^n \left(\frac{n}{n-1}\right)^2 \left\{ (Y_i - \bar{Y})^2 - s_n^2 \right\}^2 = \left(\frac{n}{n-1}\right)^3 \frac{(m_4 - s_n^4)}{n},$$

where $m_4 = n^{-1} \sum_{i=1}^n (Y_i - \bar{Y})^4$ is the sample central fourth moment, which estimates the population fourth moment $\mu_4 = E(Y_1 - \mu)^4$. Thus, we see that in large samples $\hat{V}_J$ is estimating the asymptotic variance of s_n^2 given by $(\mu_4 - \sigma^4)/n$.

Recall the correlation estimates of [The bootstrap](#) section for the 13 class evaluations. The bootstrap gave $\hat{V}_{\text{Boot}} = 0.013$ for the Pearson correlation and $\hat{V}_{\text{Boot}} = 0.022$ for the Spearman correlation. The jackknife gives $\hat{V}_J = 0.013$ and $\hat{V}_J = 0.014$, respectively. It is curious that $\hat{V}_J = 0.014$ is so much smaller than $\hat{V}_{\text{Boot}} = 0.022$ for the Spearman correlation. [Efron and Stein \(1981\)](#) gave the interesting result that often $\hat{V}_J$ is biased upwards, that is, $E(\hat{V}_J) \geq \text{Var}(\hat{\theta})$, but there is no general result suggesting which of $\hat{V}_{\text{Boot}}$ or $\hat{V}_J$ will be larger.

Further comments

The jackknife can be extended to multiple independent samples, regression settings, and dependent samples. Generally it can be used for variance estimation in most places where the bootstrap can be used, but not for estimating the variance of the sample median. It is not as intuitive as the bootstrap to extend to more complicated situations, but it is one of the popular methods available for variance estimation in complex surveys ([Rust and Rao, 1996](#)). [Wu \(1986\)](#) gives extensions for regression. [Miller \(1974\)](#) provides an early review of the jackknife, but accessible introductions are in [Efron and Tibshirani \(1993\)](#) and [Boos and Stefanski \(2013, Ch. 10\)](#). Asymptotic theory is given in [Shao and Tu \(1995\)](#). R code may be found in the packages `bootstrap` (v2019.6, [Tibshirani et al., 2019](#)) and `MonteCarlo.se` ([Boos et al., 2019](#)).

Permutation tests

Permutation tests were invented by R. A. Fisher sometime in the early 1930s with examples found in his books (e.g., Fisher 1934, 1935). The exact first mention seems a mystery, but the main scope of application was quickly discovered by others, for example, Pitman (1937a,b, 1938) and Welch (1937), and the general theorem on validity given by Hoeffding (1952). See Berry et al. (2011) for a detailed history. Then the permutation method languished for many years except for use with rank methods where it provided one way to compute null distributions of rank-based test statistics like the Wilcoxon Signed Rank and Wilcoxon Rank Sum statistics. With increased computing power, the exact permutation distributions became available in certain situations, but more importantly, it was discovered that one only need to randomly sample from the full set of permutations. So computations are no longer an issue.

Before getting into details and examples, the key points are these:

1. The permutation method can only be used in 5 basic designs (plus stratified versions and other extensions). Contingency tables belong to these designs but they are presented in a different form, so we add them as a separate situation below.
 - (a) One sample, where the test statistic has a symmetric distribution around the null hypothesis value. Or two paired samples, where differences within pairs are used. Key examples: paired t -test, Wilcoxon Signed Rank Test.
 - (b) Two independent samples, where each sample comes from the same population under the null hypothesis. Key examples: two-sample pooled variance t -test, Wilcoxon Rank Sum Test.
 - (c) k independent samples, where each sample comes from the same population under the null hypothesis. Key examples: one-way analysis of variance F test for no mean differences, Kruskal-Wallis Rank Test.
 - (d) k treatments in a randomized complete block design. Key examples: two-way analysis of variance F test for no treatment mean differences, Friedman Rank Test.
 - (e) Random (X, Y) pairs. Key examples: Pearson correlation, simple linear regression t -test for slope = 0, Spearman and Kendall Rank Tests of Independence.
 - (f) m by k contingency tables. Key examples: McNemar's Test (2 by 2 tables, paired binary samples), Fisher's Exact Test (2 by 2 tables, independent or paired binary samples), Extension of Fisher's Exact Test (independence of two nominal-valued variables), Kruskal-Wallis Test (k independent samples of one ordinal-valued variable), Spearman and Rank Correlation Tests of Independence (two paired ordinal-valued variables).
2. There are no distributional *type* restrictions like normal or exponential. So the method will apply to any type of distribution as long as the basic random sampling restrictions of the above 5 designs hold.
3. There are no restrictions on the test statistic used. That is, one can dream up any test statistic for the above 5 designs, and the permutation method will make its use valid, that is, it will have correct Type I error properties. However, the basic permutation theory says nothing about power properties (Type II errors), that is, which test statistics will have good rejection rates under alternatives.

One sample (symmetry) or two paired samples

Fisher introduced the permutation approach for the matched-pairs problem in a discussion of Darwin's data on self-fertilized and cross-fertilized plants. There were 15 pairs of plants, and the differences

$$49, -67, 8, 16, 6, 23, 28, 41, 14, 29, 56, 24, 75, 60, -48$$

have mean $\bar{D} = 20.933$, $s = 37.744$, and $t = 2.148$ for testing $H_0 : \mu_D = 0$ versus $H_a : \mu_D \neq 0$, where μ_D is the population mean difference. The two-sided p -value is 0.0497 from the t table with 14 degrees of freedom. Alternatively, consider Fisher's permutation argument. There were 2^{15} possible random assignments of types of seeds to the 15 blocks of size 2. Thus, Fisher considered all 2^{15}

sums $\sum_{i=1}^{15} D_i$, where D_i is the i th difference and D_i is replaced by $-D_i$ in all ways possible (because switching X_i and Y_i changes $D_i = X_i - Y_i$ to $-D_i = Y_i - X_i$). For example, here are three such modifications:

$$\begin{aligned} & -D_1, D_2, \dots, D_{15}, \\ & -D_1, -D_2, \dots, D_{15}, \\ & -D_1, -D_2, \dots, D_{15}. \end{aligned}$$

Fisher found only $835 + 28 = 863$ which are greater than or equal to the observed sum = 314. The two-sided p -value is $(2) (863)/32,768 = 0.0527$ (by symmetry there are 863 sums ≤ -314). Note that $t = \sqrt{n}\bar{D}/s$ is permutationally equivalent to $\sum_{i=1}^{15} D_i$ because t is a monotonic function of $\sum_{i=1}^{15} D_i$ that depends on $\sum_{i=1}^{15} D_i^2$, which is constant over all 2^{15} permutations.

Let us consider the theory behind Fisher's approach. The population null model is that the differences $D_1, \dots, D_n$ are independent, each with a symmetric distribution about some θ_0 ; often $\theta_0 = 0$. The distributions do not need to be the same, merely symmetric about θ_0 . Thus $D_i - \theta_0$ and $-(D_i - \theta_0)$ have the same distribution under the null hypothesis that θ_0 is the center of the D_i distribution. So there are 2^{15} ways of manipulating the original sample by multiplying by pluses and minuses, all resulting

in samples with exactly the same joint distribution under the null hypothesis. We call these modifications of the sample *permutations* even though in this case they are not permutations.

Two independent samples

Let the samples be labeled $X_1, \dots, X_m$ and $Y_1, \dots, Y_n$. For permutation tests, the null hypothesis is that the samples come from identical populations. This is easily justified when randomly assigning a batch of experimental units to two treatments, but it can be used with observational data if that “equal-under-the-null” assumption is justified. Then, the data modifications are to partition the full data $(X_1, \dots, X_m, Y_1, \dots, Y_n)$ into all possible X and Y samples of size m and n ; for example, exchanging X_1 and Y_1 gives $(Y_1, X_2, \dots, X_m)$ and $(X_1, Y_2, \dots, Y_n)$. There are $(m+n)/(m!n!)$ such sets of two samples.

General notation and approach

In each situation, we use N for the total number of data points and M_N for the number of unique modifications that preserve the same joint distribution of the data under the null hypothesis. For the first example above (paired samples), $N = n$ and $M_N = 2^n$. For two independent samples, $N = m + n$ and $M_N = (m+n)/(m!n!)$. For k independent samples of size $n_1, n_2, \dots, n_k$, $N = n_1 + n_2 + \dots + n_k$, and $M_N = N!/(n_1!n_2!\dots n_k!)$. For the randomized complete block design with n blocks and k treatments, $N = n * k$, and $M_N = (k!)^n$. Finally, for n pairs (X, Y) and the test of independence, $N = 2n$ and $M_N = n!$.

For each situation and any statistic T , we calculate T for all the permutations, resulting in $T_1, \dots, T_{M_N}$. Let T_0 be the statistic calculated on the original data, and suppose that we reject the null hypothesis for large values of T . Then the permutation p -value is

$$p_{\text{perm}} = \frac{[\text{Number of } T_i \geq T_0]}{M_N}.$$

The permutation theory guarantees that if you do formal testing as “reject the null if $p_{\text{perm}} \leq \alpha$,” then $P(\text{Type I error}) \leq \alpha$. Note that the nonparametric bootstrap method cannot give this kind of guarantee. If we reject the null hypothesis for small values of T , then we merely change $\geq$ to $\leq$ in p_{perm} above. For two-sided tests, we often work with absolute values or squared versions like $|t|$ or t^2 .

Because the number of permutations M_N grows rapidly with N , we typically randomly sample (with replacement) B of the permutations, compute T for each sampled permutation resulting in $T_1^*, \dots, T_B^*$, and estimate p_{perm} with

$$\hat{p}_{\text{perm}} = \frac{[\text{Number of } T_i^* \geq T_0]}{B}.$$

The numerator of $\hat{p}_{\text{perm}}$ is binomial (B, p_{perm}) distributed so that $E(\hat{p}_{\text{perm}}) = p_{\text{perm}}$ and the estimated standard deviation of $\hat{p}_{\text{perm}}$ is $\sqrt{\hat{p}_{\text{perm}}(1 - \hat{p}_{\text{perm}})/B}$. I suggest choosing B large enough so that the estimated standard deviation is less than the first non-zero digit of $\hat{p}_{\text{perm}}$.

Further comments on permutation tests

Why are permutation tests not used more? The core of statistical applications use linear model theory where t and F approximations are usually quite close to permutation results. How close is close? The overriding point is that the sample-to-sample variability of any kind of p -value is quite large compared to the difference between good approximate p -values and the true permutation p -value p_{perm} or its estimate $\hat{p}_{\text{perm}}$ (see, e.g., [Boos and Stefanski, 2011](#)). So approximations are often good enough for inferential purposes. However, with categorical data, contingency tables, and rank tests, the chi-squared approximations are not as good, and permutation methods are very useful. One area where permutation methods are especially useful but not well-known is in meta-analysis (see [Follmann and Proschan, 1999](#)). Some books on permutation tests include [Edgington et al. \(2007\)](#), [Good \(1994\)](#), and subsequent editions), [Berry et al. \(2014\)](#), and [Boos and Stefanski \(2013, Ch. 12\)](#). The history of permutation tests with many references may be found in [Berry et al. \(2011\)](#), and [Berry et al. \(2018\)](#).

Summary

Resampling is a way to estimate the sampling distribution of random quantities computed from random samples. The main applications are for estimating the bias and variance of estimators, give confidence intervals for population parameters, and estimate the null distributions of hypothesis testing statistics.

1. Chronologically, permutation tests appeared first, in the 1930s. The scope of the permutation approach is very limited, applying to basically only five sampling designs and their extensions. However, for the those designs, the approach is *distribution-free* (does not depend on parametric family assumptions like normality) and is *statistic-inclusive* (any test statistic can be used). Moreover, the level- α control of Type I error holds for all samples sizes, small and large. In practical applications, it is simplest to estimate

the p -value by sampling from the set of permutations, and choosing B large enough to make the Monte Carlo standard error small.

2. The jackknife appeared next historically in development. For samples of size n , the i th resample of size $n - 1$ is created by dropping Y_i from the sample. The statistic of interest, say T , is then computed for each of the n resamples of size $n - 1$, and the jackknife variance estimate $\hat{V}_1$ is formed from the sample variance of those T^* . $\hat{V}_1$ is only theoretically justified in large samples and for regular estimators, but typically it performs well in small samples.
3. The bootstrap appeared last of the three main resampling methods, introduced by Efron in his famous 1979 paper. The nonparametric bootstrap is based on sampling from the sample as if it were a population. It can estimate virtually any aspect of regular estimators and test statistics. For variance estimation, its scope is wider than the jackknife because it can handle non-smooth estimators like the sample median. Otherwise, choosing between the nonparametric bootstrap and the jackknife is mostly personal preference—in large samples, such as found in Monte Carlo studies, they give almost identical results. However, the bootstrap can help with a myriad of other statistical inference needs such as confidence intervals and hypothesis tests. When compared with permutation tests on their home turf, the nonparametric bootstrap is not as good because all results are justified only in large samples and are limited to regular test statistics. However, there are many situations outside the home base of permutation tests where the bootstrap can be used. Typical recommendations for bootstrap resample sizes B are 100 to 1000 for variance estimation and 2000 or more for confidence intervals and percentile estimation. The “official” bootstrap estimate is the result of letting B approach infinity. If computing time is not a problem, choosing a large B can help others match results published in papers.

The parametric bootstrap is based on assuming a family of distributions like the normal (μ, σ^2) distribution, and drawing bootstrap resamples from the family with estimated parameters. It can handle nonregular statistics and also give exact test results as we saw with goodness-of-fit testing. However, the parametric bootstrap is less used in applications because we often want to avoid parametric assumptions. For example, we might choose a parametric family to get a maximum likelihood estimator but then use the nonparametric bootstrap to assess variability.

Overview

In Bayesian statistics, probability is viewed as a universal gauge for uncertainty (O'Hagan, 2004, 2008). Not only is it able to describe randomness due to sampling—the source of variation dominating the frequentist definition of probability, it also broadly quantifies the lack of precise knowledge in any aspect of the data generating mechanism. For example, it is valid in Bayesian statistics to formalize one's personal belief on the values of model parameters as a probability distribution, whereas in frequentist statistics model parameters are treated as non-random quantities attached to data generating models and thus are not personal. As a consequence, Bayesian inference focuses on how the prior belief about parameters is updated after acquiring data and hence is “post-data” in nature. In contrast, frequentist inference concerns the stochastic behavior of statistical procedures over repeated sampling; such inference is “pre-data” as probability statements are made for the generative process that produces the observed data (Hinkley, 1983). Although Bayesian and frequentist statistics are based on fundamentally different philosophies, the discrepancy may be hardly noticeable in large samples (van der Vaart, 1998).

Prior specification is crucial for Bayesian inference in both subjective and objective modes. In more subjective uses of Bayesian statistics, analysts rely on probability distributions to make coherent decisions under uncertainty (DeGroot, 1970; Savage, 1954). Accordingly, a prior distribution should properly encode noisy *a priori* knowledge about the statistical model, which is then updated following the Bayes' rule when new data are observed. It is also possible to form priors when no *a priori* information is available (Berger, 2006; Kass and Wasserman, 1996). Nevertheless, there is no ubiquitous criterion of objectivity and hence no unique definition of objective priors.

In spite of the long-standing origin that can be traced back to the 18th century (Bayes, 1763), Bayesian methodology has not been popularized in education research and practices until recent decades due to computational intensity. Only in very few lucky cases, e.g., by conjugacy of well-known families of distributions, can one have closed-form expressions for the posterior density and the summary quantities (e.g., mean and variance) thereof. More frequently, Monte Carlo sampling techniques, such as Markov chain Monte Carlo (MCMC; Metropolis et al., 1953) and sequential Monte Carlo (SMC; Del Moral et al., 2006) must be invoked to generate random samples from the posterior distribution, from which approximations to summary quantities are constructed.

Statistical inference made from models that are incompatible with the observed data can be misleading. In the Bayesian framework, model-data fit can be conveniently assessed by comparing the observed data with the posterior distribution of the predictive data (Rubin, 1984). When there are competing hypotheses on the joint model for data and parameters, analysts often need to identify the optimal candidate in a principled manner. Model comparison criteria in Bayesian statistics can be defined based on the accuracy of out-of-sample prediction, the marginal likelihood of the observed data implied by joint model, and so forth (Kass and Raftery, 1995; Spiegelhalter et al., 2002).

Bayesian inference

Posterior distribution

The primary task of Bayesian inference is to specify the joint distribution of data $\mathbf{y} \in \mathcal{Y}$ and parameters $\boldsymbol{\theta} \in \Theta$, where $\mathcal{Y}$ and Θ denote data and parameter spaces, respectively. Let $f(\boldsymbol{\theta}, \mathbf{y})$ be the density¹ of the joint distribution, which can be factorized by the definition of a conditional density:

$$f(\boldsymbol{\theta}, \mathbf{y}) = f(\boldsymbol{\theta})f(\mathbf{y}|\boldsymbol{\theta}) \quad (1)$$

In Eq. (1), $f(\boldsymbol{\theta})$ is the marginal density of $\boldsymbol{\theta}$ and is commonly referred to as the *prior* density, which reflects one's uncertainty about model parameters prior to observing any data. Subjective beliefs, expert opinions, and/or existing empirical results may all serve as sources for prior specification. The second component on the right-hand side of Eq. (1), $f(\mathbf{y}|\boldsymbol{\theta})$, is termed the *likelihood*, which indicates how the data values $\mathbf{y}$ are likely to be observed given the parameter values $\boldsymbol{\theta}$. The likelihood uniquely characterizes the data generating mechanism and plays the central role in both frequentist and Bayesian inference.

For making inference about parameters $\boldsymbol{\theta}$, one is often more interested in the density of the "inverse problem," i.e., $f(\boldsymbol{\theta}|\mathbf{y})$, which expresses one's updated or adjusted belief of parameters $\boldsymbol{\theta}$ after seeing the observed data $\mathbf{y}$. In modern terminology, $f(\boldsymbol{\theta}|\mathbf{y})$ is referred to as the *posterior* density. Using the relationship of joint and conditional densities in the other direction, we arrive at the celebrated Bayes' (1763) formula:

$$f(\boldsymbol{\theta}|\mathbf{y}) = \frac{f(\boldsymbol{\theta}, \mathbf{y})}{f(\mathbf{y})} = \frac{f(\boldsymbol{\theta})f(\mathbf{y}|\boldsymbol{\theta})}{f(\mathbf{y})} \quad (2)$$

In Eq. (2), the denominator $f(\mathbf{y})$ is often called the *marginal likelihood* of $\mathbf{y}$, which by definition can be further expressed as

$$f(\mathbf{y}) = \int_{\mathcal{Y}} f(\boldsymbol{\theta}, \mathbf{y}) d\mathbf{y} = \int_{\mathcal{Y}} f(\boldsymbol{\theta})f(\mathbf{y}|\boldsymbol{\theta}) d\mathbf{y} \quad (3)$$

It is remarked that $f(\mathbf{y}) \neq 0$ is implicitly assumed in the Bayes' formula Eq. (2): This is not a restrictive assumption because any reasonable specification of $f(\boldsymbol{\theta}, \mathbf{y})$ should guarantee that data values arbitrarily close to the observed instance $\mathbf{y}$ can be generated with a positive probability.

A running example

As an illustration, we consider a one-parameter probit regression example (Agresti, 2013, Section 7.1). Let $\mathbf{y} = (y_1, \dots, y_n)'$ be a collection of n independent response variables. Each $y_i \in \{0, 1\}$ is a Bernoulli trial with success probability

$$\pi_i(\boldsymbol{\theta}) = P\{y_i = 1|\boldsymbol{\theta}\} = \Phi(\boldsymbol{\theta} + x_i) \quad (4)$$

in which Φ denotes the standard normal distribution function, x_i represents the known covariate value for observation i , and $\boldsymbol{\theta}$ is the intercept parameter.² By independence, the likelihood can be expressed as

$$f(\mathbf{y}|\boldsymbol{\theta}) = \prod_{i=1}^n \pi_i(\boldsymbol{\theta})^{y_i} [1 - \pi_i(\boldsymbol{\theta})]^{1-y_i} \quad (5)$$

Consider $n = 2$ and a standard normal prior $f(\boldsymbol{\theta})$.³ The data space $\mathcal{Y}$ comprises four response patterns: $(0, 0)'$, $(1, 0)'$, $(0, 1)'$, and $(1, 1)'$. As Fig. 1 depicts, the joint density $f(\boldsymbol{\theta}, \mathbf{y})$ is the product of the prior and likelihood. The area under each $f(\boldsymbol{\theta}, \mathbf{y})$ equals to the marginal likelihood $f(\mathbf{y})$: The four areas add up to one, which is the total area under the standard normal prior. The posterior is obtained by renormalizing the corresponding joint density so that the area under the curve is one.

¹The term "density" is slightly abused to refer to either the probability density function for a continuous random variable or the probability mass function for a discrete random variable. The letter f is reserved as a generic notation for density functions.

²For ease of illustration, we fix the slope for the covariate to 1. In most applications of probit analysis, however, both the intercept and slope are estimated.

³The covariate values are fixed at $x_1 = 0.5$ and $x_2 = -1$.

Fig. 1 Prior $f(\theta)$, likelihood $f(\mathbf{y}|\theta)$, joint density $f(\theta, \mathbf{y})$, and posterior $f(\theta|\mathbf{y})$ for the probit regression example ($n = 2$). There are in total four possible response patterns: $\mathbf{y} = (0, 0)'$, $(0, 1)'$, $(1, 0)'$, and $(1, 1)'$. The standard normal prior is highlighted by thick solid lines in gray color. Likelihoods, joint densities, and posteriors for different response patterns are shown in different line types.

A decision-theoretic treatment

Given the posterior of θ given $\mathbf{y}$, various kinds of inference can be made for the parameters θ , transformations of θ , or future data whose generative process depends on θ . Inferential procedures can be conveniently presented and evaluated under the decision theoretic framework (Berger, 1985), which we now elaborate.

Decision rule, loss, and risk

A statistical decision can be formally defined as a map d from the data space $\mathcal{Y}$ to the action space $\mathcal{A}$. The action space is determined by the type of statistical inference of interest: For example, $\mathcal{A} = \Theta$ if one aims to find a point estimator of θ . Given a pair of data $\mathbf{y} \in \mathcal{Y}$ and parameters $\theta \in \Theta$, every statistical decision $d(\mathbf{y}) \in \mathcal{A}$ carries a “cost” measured by a non-negative *loss function* $L(d(\mathbf{y}), \theta)$ —as the name suggests, a better decision comes with a smaller loss. Because data $\mathbf{y}$ and parameters θ are both stochastic in the Bayesian configuration, one may evaluate the overall quality of a decision rule d by the *Bayes risk*:

$$R(d) = \iint_{\Theta \times \mathcal{Y}} L(d(\mathbf{y}), \theta) f(\theta, \mathbf{y}) d\theta d\mathbf{y} \quad (6)$$

which is the expectation of the loss function under the joint density. We may further rearrange Eq. (6) as

$$R(d) = \int_{\mathcal{Y}} L(d(\mathbf{y}), \theta) f(\theta|\mathbf{y}) f(\mathbf{y}) d\theta d\mathbf{y} = \int_{\mathcal{Y}} \underbrace{\left\{ \int_{\Theta} L(d(\mathbf{y}), \theta) f(\theta|\mathbf{y}) d\theta \right\}}_{\rho(d, \mathbf{y})} f(\mathbf{y}) d\mathbf{y} \quad (7)$$

In the second line of Eq. (7), the term $\rho(d, \mathbf{y})$ is labeled the *posterior risk*, which amounts to the posterior expectation of the loss function. As a corollary of Eq. (7), a decision rule d that minimizes the posterior risk for every $\mathbf{y}$ also minimizes the Bayes risk.

Point estimation

Let $d(\mathbf{y})$ be a point estimator of θ , and $\mathcal{A} = \Theta$. We may define the loss function by $L(d(\mathbf{y}), \theta) = \|d(\mathbf{y}) - \theta\|$ with any norm $\|\cdot\|$ on Θ . For instance, the (squared) L^2 -norm corresponds to the squared error loss, and the L^1 -norm corresponds to the absolute error loss. A point estimator that minimizes the Bayes risk Eq. (6) is considered optimal. It can be shown that the posterior mean, also known as the expected *a posteriori* (EAP) estimator, minimizes the posterior risk Eq. (7) under the squared error loss; similarly, the posterior median is optimal under the absolute error loss. More generally, we might be interested in estimating transformed parameters defined by a map $\eta: \Theta \rightarrow H$, $\theta \mapsto \eta(\theta)$. Now the action space $\mathcal{A}$ becomes the transformed parameter space H ; the loss and risk functions can be defined accordingly with a suitable norm on H .

In our running example, suppose that we observed the response pattern $\mathbf{y} = (1, 0)'$. The posterior density of θ and the EAP estimator $\hat{\theta}(\mathbf{y}) = E(\theta|\mathbf{y}) = \int_{\Theta} \theta f(\theta|\mathbf{y}) d\theta = 0.12$ are graphed in the first panel of Fig. 2. We also consider estimating the expected total of y_1 and y_2 :

$$\eta(\theta) = E(y_1 + y_2|\theta) = \pi_1(\theta) + \pi_2(\theta) \quad (8)$$

which is a strict monotonic transform of θ . The EAP estimator of $\eta(\theta)$ is $\hat{\eta}(\mathbf{y}) = E(\eta(\theta)|\mathbf{y}) = \int_{\Theta} \eta(\theta) f(\theta|\mathbf{y}) d\theta = 0.93$. All the integrals involved in the above calculations do not have closed-form solutions and thus are approximated using numerical quadrature.

Fig. 2 Inference made based on the observed response pattern $\mathbf{y} = (1, 0)'$. First panel: Expected *a posteriori* estimator of θ . Second panel: Hypothesis testing of $\Theta_0 : \theta \leq 1$ versus $\Theta_1 : \theta > 1$. Third panel: 95% highest posterior density region. Fourth panel: Predictive probabilities for the four future response patterns.

Hypothesis testing

Let the null hypothesis Θ_0 and the alternative hypothesis Θ_1 be disjoint subsets of the parameter space Θ . A hypothesis test is conducted to decide whether Θ_0 or Θ_1 is favored given one's prior knowledge as well as the observed data. The binary action space for the testing problem is denoted $\mathcal{A} = \{\Theta_0, \Theta_1\}$. Accordingly, a decision rule d maps data $\mathbf{y}$ to one of the two possible actions, and the loss function for evaluating $d(\mathbf{y})$ may take the following form:

$$L(d(\mathbf{y}), \theta) = \begin{cases} c_1, & \theta \in \Theta_0 \text{ and } d(\mathbf{y}) = \Theta_1 \\ c_2, & \theta \in \Theta_1 \text{ and } d(\mathbf{y}) = \Theta_0 \\ 0, & \text{otherwise} \end{cases} \quad (9)$$

In Eq. (9), c_1 and c_2 are positive constants assigned to penalize Type I and Type II error, respectively. If we set $c_1 = c_2$, which equally weighs the two types of error, then the optimal decision that minimizes the posterior risk boils down to selecting the subspace with a larger posterior probability.

In the probit regression example, suppose that we are interested in testing $\Theta_0 = \{\theta : \theta \leq 1\}$ against $\Theta_1 = \{\theta : \theta > 1\}$ given the observed response pattern $\mathbf{y} = (1, 0)'$; see the second panel of Fig. 2. The posterior probabilities for the two subspaces are $P\{\Theta_0|\mathbf{y}\} = 0.89$ and $P\{\Theta_1|\mathbf{y}\} = 0.11$, which clearly favors Θ_0 .

Set estimation

A set estimate of θ , denoted $d(\mathbf{y})$ using the decision-theoretic notation, is a data-dependent subset of the parameter space Θ . The corresponding action space contains all subsets of Θ , i.e., $\mathcal{A} = 2^\Theta$. Averaged over the joint distribution of data and parameters, a good set estimate is expected to strike a balance between a high chance to include θ and a small size (Winkler, 1972). It then motivates the following loss function:

$$L(d(\mathbf{y}), \theta) = 1\{\theta \notin d(\mathbf{y})\} + w|d(\mathbf{y})| \quad (10)$$

in which $1\{B\} = 1$ if event B holds and 0 otherwise, $|A|$ denotes the size of set $A \subset \Theta$, and $w > 0$ is the weight controlling the relative importance of coverage and size. Eq. (10) gives rise to the following posterior risk:

$$\rho(d, \mathbf{y}) = P\{\theta \notin d(\mathbf{y})|\mathbf{y}\} + w|d(\mathbf{y})| \quad (11)$$

One may optimize Eq. (11), which implies a compensatory relation between the coverage and size of the resulting set estimate, upon observing data $\mathbf{y}$. As an alternative, one may fix a required level of posterior probability covered by $d(\mathbf{y})$ while optimize only for its size. This latter approach is more commonly seen in practice and leads to the so-called *high posterior density* (HPD) regions (Box and Tiao, 1973, p. 122).

In the probit regression example, the 95% HPD interval estimate⁴ of θ is defined by

$$d(\mathbf{y}) = \{\theta : f(\theta|\mathbf{y}) \geq \lambda\} \quad (12)$$

in which λ satisfies $P\{f(\theta|\mathbf{y}) \geq \lambda|\mathbf{y}\} = 0.95$; both λ and the end points of the HPD interval need to be determined numerically. For the response pattern $\mathbf{y} = (1, 0)'$, as shown in the third panel of Fig. 2, the 95% HPD interval is $[-1.32, 1.55]$, and the associated $\lambda = 0.08$.

⁴Here, the HPD region is an interval because the posterior density is unimodal.

Prediction

Sometimes, it is desired to make predictive inference about data that have not yet been observed. Let $\mathbf{z} \in \mathcal{Z}$ be the future data: $\mathbf{z}$ and $\mathbf{y}$ need not be independent or identically distributed in general, but we assume that the conditional likelihood of $\mathbf{z}$ given $\mathbf{y}$, denoted $f(\mathbf{z}|\mathbf{y}, \boldsymbol{\theta})$, is governed by the same set of parameters $\boldsymbol{\theta}$. The *posterior predictive density* for future data given the observed data is

$$f(\mathbf{z}|\mathbf{y}) = \int_{\Theta} f(\boldsymbol{\theta}|\mathbf{y})f(\mathbf{z}|\mathbf{y}, \boldsymbol{\theta})d\boldsymbol{\theta} \quad (13)$$

To recast Bayesian prediction in the decision-theoretic framework, we just need to treat $(\boldsymbol{\theta}', \mathbf{z}')'$ as “augmented parameters” defined on $\Theta \times \mathcal{Z}$ and apply suitable loss functions on the $\mathbf{z}$ -marginal.

In the probit regression example, suppose that the future data consist of two additional responses with the same covariate values x_1 and x_2 —that is, $\mathbf{z}$ is an independent and identically distributed (i.i.d.) copy of $\mathbf{y}$. In this case, the predictive probability Eq. (13) reduces to $f(\mathbf{z}|\mathbf{y}) = \int_{\Theta} f(\boldsymbol{\theta}|\mathbf{y})f(\mathbf{z}|\boldsymbol{\theta})d\boldsymbol{\theta}$. Given the responses $\mathbf{y} = (1, 0)'$ to the two original items, the predictive probabilities for the four possible future patterns were computed and plotted in the last panel of Fig. 2.

Connection with frequentist inference

Notwithstanding the disparity in their underlying philosophies, Bayesian and frequentist approaches often yield comparable results in many applications, especially when the likelihood is formed based on a large number of independent samples. Let the data $\mathbf{y}$ be composed of n independent observations $(y_1, \dots, y_n)'$ so that the likelihood is subject to the factorization $f(\mathbf{y}|\boldsymbol{\theta}) = \prod_{i=1}^n f_i(y_i|\boldsymbol{\theta})$, where

$f_i(y_i|\boldsymbol{\theta})$ denotes the per-observation likelihood. Suppose for the moment that the sample data $\mathbf{y}$ are generated under $f(\mathbf{y}|\boldsymbol{\theta}_0)$ with true parameters $\boldsymbol{\theta}_0$, which is a standard frequentist setup. It can be established under virtually no additional assumption that the posterior distribution $f(\boldsymbol{\theta}|\mathbf{y})$ converges weakly to a point mass concentrated at $\boldsymbol{\theta}_0$ as the sample size n increases—a result known as the Doob’s Consistency Theorem (Doob, 1949). Under stronger regularity conditions, the Bernstein-von Mises Theorem (Le Cam and Yang, 1990; van der Vaart, 1998) states that the posterior distribution of $\boldsymbol{\theta}$ approaches the (random) normal measure $\mathcal{N}(\hat{\boldsymbol{\theta}}_n(\mathbf{y}), \mathcal{I}_n(\boldsymbol{\theta}_0)^{-1})$ as $n \rightarrow \infty$, in which $\hat{\boldsymbol{\theta}}_n(\mathbf{y})$ denotes the maximum likelihood estimator (MLE) and $\mathcal{I}_n(\boldsymbol{\theta}_0)$ denotes the sample Fisher information matrix. As such, Bayesian point estimators, such as the posterior mean, behave essentially identically to the MLE in large samples, and Bayesian credible sets have asymptotically the correct frequentist coverage.

To illustrate the large-sample concordance of frequentist and Bayesian inference in our probit regression example, we fixed $\theta_0 = -1$ and simulated 40 independent responses variables.⁵ In Fig. 3, we contrast the normalized likelihood and posterior, as well as the MLE and the posterior mean (i.e., EAP), computed using the first two, first 20, and all 40 response variables. As n increases, the normalized likelihood and posterior becomes closer to one another, and both the MLE and EAP tend to $\theta_0 = -1$.

Fig. 3 Prior (gray solid), likelihood (black dashed), and posterior (black solid) for $n = 2, 20$, and 40 . Because the likelihood is smaller than the prior and posterior by many orders of magnitude when n is large, we normalize the likelihood so that the area under the curve is one. The maximum likelihood estimator (MLE) and the expected *a posteriori* (EAP) estimator are marked as the solid and dashed vertical lines, respectively.

⁵The covariates were randomly generated: $x_i \sim \text{Uniform}(0.5, 2)$, $i = 1, \dots, 40$. Once sampled, those values were treated as fixed when making inference about $\boldsymbol{\theta}$.

Prior specification

Uncertainty quantification

Howson and Urbach (2006) argued that Bayesian inference serves as a universal foundation for scientific inductions: In particular, it dictates how knowledge is accumulated or adapted in the emergence of new evidence. In line with the perspective of inductive reasoning, a prior distribution of model parameters should be specified to reflect the analyst's preknowledge and the associated degree of uncertainty. Though it is not invalid to select priors based solely on subjective beliefs, scientific inquiries often call for more principled prior elicitation protocols to reduce the impact of personal bias. For example, prior information may be elicited from content experts by the techniques of "elaboration" (O'Hagan et al., 2006). It may also be possible to find meta-analytical evidence or even historical data sets pertaining to the statistical model under investigation. Methods that turn historical information into priors, such as meta-analytic-predictive prior and power prior, have been extensively studied in the literature (Ibrahim and Chen, 2000; Schmidli et al., 2014).

Objective Bayes

When no *a priori* knowledge is present, one may still be able to conduct Bayesian inference using objective priors, which are derived based on various underpinnings of "objectivity" or "noninformativeness"; see Kass and Wasserman (1996) for a comprehensive review. One classic rule is the principle of insufficient reason, also known as the Bayes-Laplace postulate, which assigns "equal likelihood" to all parameter values to indicate absence of prior knowledge. In case the parameter space is unbounded so that a uniform prior is improper, a popular workaround amounts to the use of diffuse proper priors, such as normal distributions with large variances (Box and Tiao, 1973, p. 23). An obvious problem for the rule of insufficient reason is that the uniform distribution fails to be invariant under reparameterization: In the probit regression example, a uniform prior on expected total $\eta(\theta)$, a nonlinear transform of the intercept θ given by Eq. (8), induces a non-uniform prior on θ . To resolve this issue, one may alternatively treat reparameterization invariance as the defining property of non-informativeness. One prominent example of this kind is Jeffreys' (1946) prior: For one-parameter problems, Jeffreys' prior is proportional to the square-root of the Fisher information. A third possible definition of objective priors is to "maximize the discrepancy" between the prior and posterior distributions. For instance, Berger and Bernardo (1989) measured the discrepancy by the expected Kullback-Leibler divergence and defined a "reference prior" via an asymptotic argument. Yet another interesting rule to define objective priors is by matching frequentist probabilities. Simply put, we would like to find prior distributions such that the resulting credible intervals attain almost exact frequentist coverage (Datta and Mukerjee, 2004; Welch and Peers, 1963).

Computation

Analytical solution by conjugacy

As discussed earlier, Bayesian decision making entails computing or approximating descriptive quantities (e.g., moments, quantiles, etc.) of the posterior distribution. For certain combinations of likelihood functions $f(\mathbf{y}|\theta)$ and prior densities $f(\theta)$, the posterior and prior distributions belong to the same family, leading to the phenomenon of *conjugacy* (Raiffa and Schlaifer, 1961). Such priors are referred to as *conjugate priors* with respect to the parameters θ for the likelihood $f(\mathbf{y}|\theta)$.

A standard textbook example of conjugacy concerns estimating the mean of a normal distribution with a known variance (Gelman et al., 2013, Section 2.5). Let $y_1^*, \dots, y_n^*$ be i.i.d. $\mathcal{N}(\theta, \sigma^2)$ data, where $\sigma^2 > 0$ is known, and $\mathcal{N}(\theta_0, \sigma_0^2)$ be the prior for the mean parameter θ . It can be shown that the resulting posterior is again normal with mean $(n\bar{y}^* \sigma_0^2 + \theta_0 \sigma^2) / (n\sigma_0^2 + \sigma^2)$ and variance $\sigma_0^2 \sigma^2 / (n\sigma_0^2 + \sigma^2)$, in which $\bar{y}^* = \sum_{i=1}^n y_i^* / n$. Inference for the mean parameter can therefore be made with ease since descriptive quantities of the normal family are often readily computable.

In certain scenarios, conjugacy, albeit not directly applicable to the likelihood of the observed data, may simplify posterior-based computations (e.g., Monte Carlo sampling) via data augmentation (Tanner and Wong, 1987). In our probit model example, we introduce i.i.d. auxiliary variables $y_i^* \sim \mathcal{N}(\theta, 1)$, $i = 1, \dots, n$, and re-express the success probability Eq. (4) as a function of both θ and y_i^* (Albert and Chib, 1993):

$$\pi_i(\theta, y_i^*) = P\{y_i^* \geq -x_i | \theta\} \quad (14)$$

The augmented Bernoulli model Eq. (14) has parameters $(\theta, \mathbf{y}^*)'$ where $\mathbf{y}^* = (y_1^*, \dots, y_n^*)'$. While the joint posterior distribution $p(\theta, \mathbf{y}^* | \mathbf{y})$ is still difficult to characterize, the conditionals $p(\theta | \mathbf{y}^*, \mathbf{y}) = p(\theta | \mathbf{y}^*)$ and $p(\mathbf{y}^* | \theta, \mathbf{y}) = \prod_{i=1}^n p(y_i^* | \theta, y_i)$ turn out to be tractable: $\theta | \mathbf{y}^* \sim \mathcal{N}(n\bar{y}^* / (n+1), 1 / (n+1))$ by the normal conjugacy result; meanwhile, Eq. (15) suggests that y_i^* follows $\mathcal{N}(\theta, 1)$ truncated to $[-x_i, \infty)$ if $y_i = 1$ and to $(-\infty, -x_i]$ if $y_i = 0$. As both conditional distributions are easy to sample from, we can generate random samples from the augmented posterior (approximately) via Gibbs sampling (Geman and Geman, 1984).

Despite the convenience that conjugate priors may bring, they can only be found for few combinations of likelihood functions and prior distributions. Forcing a specific likelihood that contains unrealistic assumptions about the data generating mechanism

ultimately results in poor model-data fit. Meanwhile, restricting to certain prior distributional families also adversely affects the flexibility in describing prior beliefs.

Monte Carlo sampling from the posterior

When it is impossible to derive closed-form expressions for posterior descriptive quantities, analysts may still count on Monte Carlo methods to make Bayesian inference. A Monte Carlo procedure generates samples (often approximately) from the target posterior distribution and estimates the desired quantities by appropriate sample statistics. For ease of exposition, suppose that the quantity of interest is the posterior expectation of the transformed parameters $\eta(\theta)$ for the rest of the current section.⁶ Usually, we are only able to analytically express the posterior density up to a normalizing constant: That is, only the joint density Eq. (1) is tractable, but the marginal likelihood Eq. (3) is not. A plethora of algorithms have been devised to tackle sampling problems of this sort. Due to limited space, we only briefly discuss two popular methods and apply them to the probit regression example.

Importance sampling

Importance sampling (IS) circumvents the difficult task of directly sampling from the target posterior. Instead, it only requires sampling from an *importance distribution* with a density $g(\theta)$ such that $f(\theta, \mathbf{y}) > 0$ implies $g(\theta) > 0$: Typically, we choose $g(\theta)$ that is easy to sample from (e.g., a normal or t distribution). It is not difficult to see that

$$E(\eta(\theta)|\mathbf{y}) = \frac{\int \eta(\theta) f(\theta, \mathbf{y}) d\theta}{\int f(\theta, \mathbf{y}) d\theta} = \frac{\int \eta(\theta) [f(\theta, \mathbf{y})/g(\theta)] g(\theta) d\theta}{\int [f(\theta, \mathbf{y})/g(\theta)] g(\theta) d\theta} = \frac{E_g[\eta(\theta) w(\theta)]}{E_g w(\theta)} \quad (15)$$

in which $w(\theta) = f(\theta, \mathbf{y})/g(\theta)$ is the *importance weight*, and E_g denotes the expectation with respect to the importance distribution. Eq. (15) indicates that it suffices to find Monte Carlo estimates of the two expectations with respect to g on the right-hand side, which can be much simpler than directly estimating the left-hand side expectation as sampling from g is assumed to be a trivial task. Note that IS remains valid even when g is not normalized, because the unknown normalizing constant appears in both the numerator and denominator and thus is canceled out on the right-hand side of Eq. (15).

We now apply IS to the probit regression example with the observed responses $\mathbf{y} = (1, 1)'$ and the item parameters listed in Footnote 1. We set the importance distribution to Cauchy with a location parameter 0.97, which is the mode of $f(\theta, \mathbf{y})$. With 10,000 Monte Carlo samples from the importance distribution, we obtained the IS estimate of $E(\theta|\mathbf{y})$ as 1.03—which coincides with the estimate based on numerical quadrature up to the second decimal place. The associated IS estimate of the target posterior density is graphed in the left panel of Fig. 4, along with the target and importance densities.

The efficiency of importance sampling hinges upon finding an importance distribution that closely approximates the target density, which becomes increasingly difficult as the dimensionality increases. One successful attempt to scale up the IS scheme to high-dimensional sampling problems is SMC (Chopin and Papaspiliopoulos, 2020; Del Moral et al., 2006). As the name

Fig. 4 Sampling from the posterior of the probit regression intercept θ given the responses $\mathbf{y} = (1, 1)'$. Left: The target, importance, and empirically estimated densities are shown in different combinations of line types and grayscales. The vertical dotted line marks the importance sampling (IS) estimate of the posterior mean. Right: A sample path produced by the random-walk Metropolis algorithm. The estimated posterior mean is highlighted by the horizontal dotted line.

⁶It is implicitly assumed that the expectation exists.

suggests, SMC constructs an importance density in a sequential manner—starting with a density that is easy to sample from and adjusting iteratively toward closer approximations to the target density. SMC has been implemented in generic software packages such as SMCTC (Johansen, 2009) and LibBi (Murray, 2013).

Markov chain Monte Carlo

MCMC sampling relies on the simulation of an ergodic Markov chain that has the target posterior as the stationary distribution (Robert and Casella, 2005, Definition 7.1). A Markov chain is characterized by a transition density $p(\theta_{t+1}|\theta_t)$, $t = 0, 1, \dots$, which designates the conditional distribution of the state at time $t + 1$ given the state at time t . We say that the target posterior $f(\theta|y)$ is the *stationary distribution* of the Markov chain if

$$f(\theta_{t+1}|y) = \int p(\theta_{t+1}|\theta_t)f(\theta_t|y)d\theta_t \quad (16)$$

Intuitively, Eq. (16) implies that if at a certain time t the marginal distribution of θ_t is exactly $f(\theta_t|y)$ then it remains unchanged forever afterward. If such a Markov chain further visits every event that has a positive posterior probability infinitely often regardless of the starting state (i.e., Harris recurrence; Meyn and Tweedie, 2009, p. 199), then it can be shown that the target expectation under the posterior is the limit of the running average along the sample path of the Markov chain: As $T \rightarrow \infty$,

$$\frac{1}{T} \sum_{t=0}^T \eta(\theta_t) \rightarrow E(\eta(\theta)|y) \quad (17)$$

almost surely regardless of the initial distribution of θ_0 . The above result is known as the Ergodic Theorem (Meyn and Tweedie, 2009, Theorem 17.1.7) and lays the groundwork for MCMC-based estimation of posterior expectations. So long as we can devise a Markov chain that satisfies the required technical conditions and let it run for sufficiently long time, the running average along the sample path is a valid estimate of the desired expectation.

One machinery to build ergodic Markov chains with desired stationary distributions is the Metropolis-Hastings algorithm (MH; Hastings, 1970; Metropolis et al., 1953). At time t , let $q(\theta_{t+1}|\theta_t)$ be the density of a *proposal distribution* such that $q(\theta_{t+1}|\theta_t) > 0$ for every θ_t and θ_{t+1} in the parameter space. An MH update is composed of the following steps: 1) generate a new state θ_{t+1} from the proposal, 2) compute the *acceptance ratio*

$$\alpha(\theta_t, \theta_{t+1}) = \min \left\{ \frac{f(\theta_{t+1}, y)q(\theta_t|\theta_{t+1})}{f(\theta_t, y)q(\theta_{t+1}|\theta_t)}, 1 \right\} \quad (18)$$

and 3) generate $u \sim \text{Uniform}[0, 1]$; retain θ_{t+1} if $u \leq \alpha(\theta_t, \theta_{t+1})$ and set $\theta_{t+1} = \theta_t$ otherwise.

To sample from the posterior given $y = (1, 1)'$ in the probit regression example, we considered a symmetric random-walk proposal $\theta_{t+1}|\theta_t \sim \mathcal{N}(\theta_t, 2^2)$. Using symmetric proposals further simplifies the calculation of Eq. (18) as the proposal densities are canceled out from the ratio. The trace plot of θ_t for $t = 1, \dots, 10000$ can be found in the right panel of Fig. 4. We estimated $E(\theta|y)$ by the average of the 10,000 generated θ_t 's, i.e., 1.04, which is very close to the previous IS estimate.

Varieties of efficient MCMC samplers have been developed based on the MH rule. For example, a Gibbs sampler (Geman and Geman, 1984) updates each coordinate of θ by sampling from its conditional distribution given the most recent values of the others. A Hamilton/hybrid Monte Carlo algorithm (HMC; Neal, 2011), as another example, generates proposals by simulating Hamiltonian dynamics on an augmented parameter space. Popular software implementations of the Gibbs and HMC samplers include BUGS (Spiegelhalter et al., 1996), JAGS (Plummer, 2015), and Stan (Stan Development Team, 2019), to name a few.

Model fit assessment and model selection

Posterior predictive checking

Posterior predictive checking (PPC) exploits the simple rationale that the observed data should be “representative” of the predictive data were the latter generated from a well-fitting model. Let $z \in \mathcal{Z}$ denote the predictive data that is an i.i.d. copy of the observed data y given model parameters θ . Recall that the joint posterior density of z and θ can be written as

$$f(z, \theta|y) = f(\theta|y)f(z|\theta) \quad (19)$$

which is a special case for the integrand of Eq. (13) under the i.i.d. assumption. Because the dimensionality of data can be high, it is often more handy to conduct PPC using a summary statistic $T(y, \theta)$, which is allowed to be dependent on both the data and parameters. Define the posterior predictive p -value (PPP-value) as

$$p_T(y) = \int \int_{T(z, \theta) \geq T(y, \theta)} f(z, \theta|y) dz d\theta \quad (20)$$

which amounts to the upper tail probability under the joint posterior of z and θ given y . An excessively low or high PPP-value indicates that the observed data is unlikely to be predicted based on the fitted posterior and hence bears witness to poor

Fig. 5 Posterior predictive distribution of test statistics and the posterior predictive p -value (PPP). The summary statistic is the total score of 20 responses; the observed total score, i.e., 9, is marked by the vertical dashed lines. The histograms were produced based on 10,000 sets of simulated predictive data. Left: Results based on the probit model with a $\mathcal{N}(0, 1)$ prior. Right: Results based on the assumption that $\theta = -0.5$.

model-data fit. A PPP-value should not be confused with a frequentist p -value because its sampling distribution is in general not uniform (Bayarri and Berger, 2000; Robins et al., 2000).

Consider the probit regression example⁷ with $n = 20$ and the observed response vector $(1, 0, 0, 0, 1, 1, 0, 0, 1, 0, 1, 0, 0, 0, 1, 1, 1, 1, 0, 0)'$. We used the total score $T(\mathbf{y}, \theta) = \sum_{i=1}^n y_i$ as the summary statistic, which equals to 9 when evaluated at the observed responses. Under the 2 PL model with a $\mathcal{N}(0, 1)$ prior, we estimated the PPP-value by simulating predictive responses conditional on 10,000 MCMC samples. A histogram of the predicted total scores is displayed in the left panel of Fig. 5; the observed total score is marked by the vertical dashed line, associated with a PPP-value of 0.676. To demonstrate how PPC is responsive to lack of fit, we also consider a poorly behaving model in which θ is fixed at -0.5 (or equivalently, specifying a point-mass prior concentrated at -0.5). The resulting PPP-value is 0.998: It can be seen from the right panel of Fig. 5 that the observed total score lies on the far lower tail of the posterior predictive distribution.

Model comparison

Out-of-sample prediction

A common strategy for model selection is to favor models that better predict future data. The accuracy of out-of-sample prediction can be measured in numerous ways. For instance, one may prefer models with high expected log predictive density (ELPD; Gelman et al., 2013), which is defined as follows:

$$\text{ELPD}(\mathbf{y}) = E_{\mathbf{z}} \log f(\mathbf{z}|\mathbf{y}) \quad (21)$$

in which $f(\mathbf{z}|\mathbf{y})$ is the posterior predictive density of future data $\mathbf{z}$ given by Eq. (13), and $E_{\mathbf{z}}$ denotes the generating distribution of $\mathbf{z}$. While the posterior predictive density can be approximated using Monte Carlo methods, the generating distribution of $\mathbf{z}$ is often not known to the analyst. If an observed $\mathbf{z}$ is available as a hold-out sample, one may estimate Eq. (21) by suitable sample statistics. There are also same-sample estimators of Eq. (21), such as the (minus) Deviance Information Criterion (DIC; Spiegelhalter et al., 2002), which do not need a hold-out sample to approximate $E_{\mathbf{z}}$.

With the same response vector we have used to demonstrate PPC, we obtained the posterior of θ conditional on the first ten responses and evaluated the corresponding log posterior predictive density of the remaining ten responses as an estimate of the ELPD. The estimated ELPD is -5.29 when a $\mathcal{N}(0, 1)$ prior is used, and -6.38 when a point-mass prior at -0.5 is used. It is then concluded that the first model has a better performance in out-of-sample prediction.

Marginal likelihood

Another useful criterion for model comparison is the marginal likelihood (Eq. 3), which reflects the propensity to reproduce the observed data under the hypothesized joint statistical model (Eq. 1). A model with a higher marginal likelihood is deemed more compatible with the observed data. It is then natural to gauge the relative fit of two competing models, whose marginal likelihood functions are respectively denoted $f(\mathbf{y}|M_1)$ and $f(\mathbf{y}|M_2)$, by the Bayes factor

⁷Item parameters were fixed at the values used to produce Fig. 3.

$$\text{BF}_{12}(\mathbf{y}) = \frac{f(\mathbf{y}|M_1)}{f(\mathbf{y}|M_2)} \quad (22)$$

$\text{BF}_{12}(\mathbf{y}) > 1$ implies that M_1 fares better than M_2 and *vice versa*. In practice, the marginal likelihood is often intractable and needs to be approximated numerically (e.g., via bridge sampling; Meng and Wong, 1996). When the sample size is large and the prior's influence is negligible, the marginal log-likelihood can be approximated by the Bayesian information criterion (BIC; Schwarz, 1978).

In the 20-item probit regression example we have been using throughout the current section, let M_1 be the joint model with a $\mathcal{N}(0, 1)$ prior and M_2 be that with a point-mass prior at -0.5 . The marginal log-likelihood values for M_1 and M_2 are -12.92 and -14.06 , respectively, leading to a Bayes factor $\text{BF}_{12}(\mathbf{y}) = \exp(14.06 - 12.92) = 3.12$. So far, all the model-fit diagnostics suggest that the model with a standard normal prior fits the observed data better.

Concluding remarks

Active research on Bayesian inferential methods includes but is not limited to model development and estimation. Convenience of Bayesian inferential framework and advances in computer software allow analysts to specify flexible models with less restrictive parametric assumptions (e.g., using process priors; Ghosh and Ramamoorthi, 2003). Recent development of Bayesian estimation techniques entails not only more general and/or efficient Monte Carlo sampling algorithms but also optimization algorithms that find good approximations to the posterior distribution and can scale up to large-size problems (e.g., variational inference; Blei et al., 2017).

Randomized trials (RTs) are the gold standard for education impact studies as a well-designed and implemented RT yields an unbiased estimate of the treatment effect (Hedges, 2017). In an RT, individuals or groups of individuals are randomly assigned to either receive the treatment that is being tested or to a comparison condition, which often utilizes the business as usual (BAU) model or program. The intervention being tested might be a reading improvement program, an online math curriculum, or a professional development program for teachers.

A RT is highly regarded in evaluating program impact because random assignment creates two or more equivalent groups based on observed or unobserved characteristics (Shadish et al., 2002). For example, the process of randomly assigning students to treatment and comparison groups would theoretically create two groups that have a similar composition of gender, race or ethnicity, and socioeconomic characteristics, or observed characteristics. In addition, random assignment also ensures that the two groups also have similar composition of unobserved characteristics, or characteristics that cannot be directly measured, such as attitude and self-efficacy (U.S. Department of Education, 2003). Creating equivalent treatment and comparison groups is an essential element in designing RTs because it partitions out the preexisting differences between groups to ensure that the observed treatment effect is the result of the intervention.

There are many components that contribute to the validity of the inferences in an RT, including the primary outcome measures and analytic plan (Shadish et al., 2002). Although all of these are important, in this article we focus specifically on the statistical power to detect an effect of a given magnitude. Statistical power is the probability of detecting an effect of a given magnitude when the true effect is non-zero. The probability of making a Type II error increases as the statistical power of the study decreases. Low statistical power may lead to invalid inferences about the presence or absence of a treatment effect.

A statistical power analysis is typically carried out to determine the probability of an RT to detect the main treatment effect (Hedges and Rhoads, 2010). The main treatment effect is the average effect of the intervention. It is often quantified in terms of an effect size, defined as the standardized difference in the mean outcome between the treatment and comparison conditions. The sensitivity of an RT to detect the main treatment effect often focuses on three overlapping topics: the standard error associated with the treatment effect, the power to detect the main effect, and the smallest effect size a study is designed to detect (Hedges et al., 2012). The latter two topics are typically the focus of *a-priori* power analysis, or a power analysis conducted during the planning stage of an RT.

Demonstrating that a study is sufficiently powered to detect an effect with a certain magnitude of interest is an imperative component of planning an RT. For example, suppose a team of researchers is developing a new online mathematics tutoring program for students and plans to test the impact of the program on mathematics achievement. They design an RT in which students are assigned to either the new online tutoring program or the current program. At the conclusion of the study, the team finds that there is no difference in mean outcomes for the two groups. A key question one might ask is whether there is no difference because the new program is not better than the current program or if the study simply is not sufficiently powered to detect a meaningful treatment effect? That is, was the sample size too small so that the estimated treatment effect was imprecise leading to a failure to reject the null hypothesis? This is not a question that one should ask at the end of a study. An *a-priori* power analysis is critical to ensure that the study is designed to enable strong evidence of whether an intervention is effective.

The purpose of this article is to present an overview of statistical power for RTs seeking to test the impact of an educational intervention. We lay the foundation by beginning with the statistical power to detect the treatment effect for a single-level RT, or a single level study in which students are the unit of random assignment. Then we discuss the statistical power to detect the treatment effect for a cluster randomized trial (CRT) or a study in which clusters, such as schools, are assigned to conditions and outcomes are

assessed at the student level. CRTs are common in impact studies in education given the nested structure of schools, students within schools, and the fact that interventions are often implemented at the school level. We end with a discussion of other types of statistical power analyses that are relevant for impact studies of educational interventions.

Power for single level RTs

Model without covariates

Recall the online mathematics tutoring program example. Students are randomly assigned to either the new program or the current program. Student mathematics achievement is the primary outcome. The level 1, or student-level model is:

$$Y_i = \beta_0 + \beta_1 T_i + e_i \quad e_i \sim N(0, \sigma^2) \quad (1)$$

Where Y_i is the mathematics score for individual $i = \{1, \dots, n\}$; β_0 is the overall mean mathematics score; β_1 is the mean difference between the treatment and comparison group or the main treatment effect; T_i is a treatment indicator with $-\frac{1}{2}$ for control and $\frac{1}{2}$ for treatment, and e_i is the residual error associated with students within a treatment condition with variance σ^2 .

The treatment effect is estimated by $\hat{\beta}_1 = \bar{Y}_E - \bar{Y}_C$, where $\bar{Y}_E$ is the mean for the treatment group and $\bar{Y}_C$ is the mean for the control group. The variance of the estimated treatment effect, which describes uncertainty of the estimate effect, is:

$$\text{Var}(\hat{\beta}_1) = \frac{\sigma^2}{P(1-P)n} \quad (2)$$

Note the variance of the treatment effect is a function of the total sample size (n), the proportion of students assigned to the treatment condition (P), and the between-student variance within a treatment condition (σ^2). The associated hypothesis test is:

$$\begin{aligned} H_0 : \beta_1 &= 0 \\ H_1 : \beta_1 &\neq 0 \end{aligned} \quad (3)$$

This test is based on the F statistic, which is defined as:

$$F_{\text{statistic}} = \frac{(MS_{\text{treatment}})}{(MS_{\text{error}})} \quad (4)$$

which denotes the relationship between treatment variance and error variance.

The power for F-test is (Kirk, 1982):

$$\begin{aligned} \text{Power} &= \text{Prob}(\text{Reject } H_0 | H_0 \text{ is false}) \\ &= \text{Prob}(F > F_{\alpha;1, J-2}) \\ &= 1 - \text{Prob}(F < F_{\alpha;1, J-2}) \end{aligned} \quad (5)$$

where $F_{\alpha;1, J-2}$ is the critical value under the null hypothesis with 1 numerator degree of freedom and $n - 2$ denominator degrees of freedom. Under the null hypothesis, the F -statistic follow the central F -distribution. Under the alternative hypothesis, the F -statistic follows the noncentral F -distribution, represented by a non-centrality parameter λ . As Eq. (6) shows, the non-centrality parameter is a function of the true treatment effect and variance of the estimated treatment effect.

$$\lambda = \frac{\beta_1^2}{\text{Var}(\hat{\beta}_1)} = \frac{\beta_1^2}{\sigma^2/[P(1-P)n]} \quad (6)$$

It is common to standardize the parameters. The standardized treatment effect can be expressed as $\delta = \beta_1/\sigma$. Set $\sigma^2 = 1$ and substituting δ into Eq. (6), we get the standardized version as:

$$\lambda = \frac{\delta^2}{1/[P(1-P)n]} \quad (7)$$

The non-centrality parameter is related to the power of the test. That is, the power increases as the λ increases. Eq. (7) suggests λ is a function of the sample size (n), the standardized treatment effect (δ), and the proportion of individuals in the treatment condition (P). As n increases, the non-centrality parameter increases, thus the power also increases. Applying this concept to the example of designing a study to test an online mathematics tutoring program, the researcher could improve the power to detect the treatment effect by increasing the number of students in the sample. This approach is often adopted by researchers since sample size typically under the control of the researcher. The power also increases as δ increases. However, the magnitude of the treatment effect is a function of the intervention and not something that is typically under the control of the researcher.

Model with a covariate

Researchers often include covariates to increase the precision of the estimated treatment effect. A pre-treatment measure, such as the students' mathematics achievement prior to receiving the intervention, is often incorporated in the model. In this case, the level-1 or the student level model is an extension of Eq. (1):

$$Y_i = \beta_0 + \beta_1 T_i + \beta_2 X_i + e_i \quad e_i \sim N(0, \sigma_{|x}^2) \quad (8)$$

where X_i is the pre-treatment covariate and β_2 is the effect associated with the covariate. The proportion of variance within a treatment condition explained by the covariate is $R_{|x}^2 = 1 - \frac{\sigma_{|x}^2}{\sigma^2}$ where σ^2 is the between-person variance within a treatment condition and $\sigma_{|x}^2$ is the variance conditional on the covariate.

Under the alternative hypothesis, the F -statistic follows a non-central F -distribution with 1 numerator and $n - 3$ denominator degrees of freedom. Note that the inclusion of a covariate reduces the degrees of freedom by 1. The standardized version of the non-centrality parameter is:

$$\lambda = \frac{n\delta^2}{1/[P(1-P)](1-R_{|x}^2)} \quad (9)$$

As Eq. (9) suggests, λ is a function of the sample size (n), the percent of variance within a treatment condition explained by the covariate ($R_{|x}^2$), the treatment effect which was standardized the same way as in the case without the covariate (δ), and the proportion of individuals assigned to the treatment condition (P). As $R_{|x}^2$ increases, the non-centrality parameter increases, thus the power also increases.

Continuing with the example of designing a study to test an online mathematics tutoring program, the researcher could include a pre-intervention measure that is highly correlated with the mathematics achievement outcome, such as the student's mathematics achievement outcome from the previous year, to increase the power of test for a given sample size and treatment effect.

Power calculation for individual level RCTs

There are two main approaches to conducting a power analysis: the sample size approach and the effect size approach. The sample size approach calculates the number of individual level units necessary for a study to detect a standardized main treatment effect of a given magnitude with a specified level of power. Note that power = 0.80 is generally the acceptable level of power for designing educational studies. Software programs, like Optimal Design Plus (Raudenbush et al., 2011), CRT Power (Borenstein and Hedges, n.d.), and PowerUp (Dong and Maynard, 2013)! are freely available for conducting power analysis for individual-level and multi-level RTs. These software programs can also be used to conduct power analysis for studies with non-randomized designs.

Suppose the researchers designing the online mathematics tutoring program are interested in determining the number of students they need to detect a treatment effect of 0.20 standard deviations (SD). Fig. 1 shows the study needs at least 790 students to detect a treatment effect of 0.20 at power = 0.80 if using a model without covariates (solid line). However, as the dashed line in Fig. 1 demonstrates, the study only needs to recruit 288 students if using a model with a pretest covariate that explains 64% of the between-student variance within a treatment condition ($R_{|x}^2 = 0.64$). This is an example where choosing appropriate covariate(s) in the model could significantly reduce the cost associated with the study. Note that we set the target treatment effect size as 0.20 SD in this example. This is based on the effect sizes of 0.20–0.30 SD commonly found in education interventions (Hill et al., 2008).

The effect size approach determines the minimum detectable effect size (MDES) a study can detect with a given number of individual-level units at a given level of power, typically power = 0.80 (Bloom, 1995). Continuing with the example of an online mathematics tutoring program, suppose the research team is limited to a sample of 500 students. They want to know the MDES assuming power = 0.80. Fig. 2 demonstrates that the MDES is 0.25 based on the model without covariates (solid line). However, the dashed line in Fig. 2 shows that the MDES is 0.15 when considering a pretest covariate that explains 64% of the between-student variance within a treatment condition. In other words, the study could detect a smaller treatment effect with power = 0.80 when the model includes a covariate, while other parameters remain constant.

Power for two-level CRTs

In a CRT, groups of individuals, or clusters are randomly assigned to treatment and comparison conditions. CRTs are common in educational settings as interventions are often implemented at the school level, e.g., whole school reform models, new curricula, and hence entire schools are assigned to condition. However, outcomes are measured at the student level creating a two-level design.

Model without covariates

Suppose a research team is interested in assessing the effectiveness of a new reading program and plans to assign schools to either implement the new program or carry on with the program that is already in place. The team seeks to determine the impact of the

Fig. 1 Power versus total number of individuals for individual-level RTs based on the model without covariates (*solid line*) and the model with a covariate that explains 64% of the between-person variance within treatment condition (*dashed line*) at $\alpha = 0.05$. The asterisks represent points where power = 0.80. Note: This figure was retrieved from Optimal Design Plus (Raudenbush et al., 2011).

Fig. 2 MDES versus total number of individuals for individual-level RTs based on the model without covariates (*solid line*) and the model with a covariate that explains 64% of the between-person variance within a treatment condition (*dashed line*) at $\alpha = 0.05$. The asterisks represent points where $n = 500$. Note: This figure was retrieved from Optimal Design Plus (Raudenbush et al., 2011).

program on student reading achievement. This is a typical two-level CRT with students nested within schools, schools randomly assigned to treatment and comparison conditions and outcome measured at the student level.

The level-1, or the student level model is:

$$Y_{ij} = \beta_{0j} + e_{ij} \quad e_{ij} \sim N(0, \sigma^2) \quad (10)$$

where Y_{ij} is the reading score for individual $i = \{1, \dots, n\}$; β_{0j} is the mean reading score for school j ; e_{ij} is the residual error associated with students with variance σ^2 .

The level 2, or the school-level model is:

$$\beta_{0j} = \gamma_{00} + \gamma_{01}T_j + r_{0j} \quad r_{0j} \sim N(0, \tau_{00}) \quad (11)$$

where γ_{00} is the grand mean reading achievement; γ_{01} is the mean difference between the treatment and control groups or the main treatment effect; T_j is a treatment indicator with $-1/2$ for control and $1/2$ for treatment, and r_{0j} is the residual error associated with schools within a treatment condition variance τ_{00} .

The treatment effect is estimated by $\hat{\gamma}_{01} = \bar{Y}_E - \bar{Y}_C$ where $\bar{Y}_E$ is the mean for the treatment group and $\bar{Y}_C$ is the mean for the control group. The variance of the estimated treatment effect is:

$$\text{Var}(\hat{\gamma}_{01}) = \frac{(\tau_{00} + \sigma^2/n)}{JP(1-P)} \quad (12)$$

Eq. (12) shows that the variance of the estimated treatment effect is a function of the between-cluster variance within a treatment condition (τ_{00}), within-cluster or between-student variance (σ^2), the sample size within a cluster (n), and the total number of clusters (J). The associated hypothesis is:

$$\begin{aligned} H_0 : \gamma_{01} &= 0 \\ H_1 : \gamma_{01} &\neq 0 \end{aligned} \quad (13)$$

and the power for the test is:

$$\begin{aligned} \text{Power} &= \text{Prob}(\text{Reject } H_0 | H_0 \text{ is false}) \\ &= \text{Prob}(F > F_{\alpha; 1, J-2}) \\ &= 1 - \text{Prob}(F < F_{\alpha; 1, J-2}) \end{aligned} \quad (14)$$

In the case of 2-Level CRT, the F -statistic = $\frac{(MS_{\text{treatment}})}{(MS_{\text{cluster}})}$. Under the null hypothesis, the F statistic follows a central F distribution with 1 numerator degree of freedom and $J - 2$ denominator degrees of freedom. Under the alternative hypothesis, the F statistic follows a non-central F distribution represented by the non-centrality parameter λ .

$$\lambda = \frac{\gamma_{01}^2}{\text{Var}(\hat{\gamma}_{01})} = \frac{JP(1-P)\gamma_{01}^2}{(\tau_{00} + \sigma^2/n)} \quad (15)$$

As in the case of the single-level RT, it is common to standardize the parameters, Hence we can re-express λ as:

$$\lambda = \frac{JP(1-P)\delta^2}{[\rho + (1-\rho)/n]} \quad (16)$$

where δ is the standardized treatment effect, $\delta = \frac{\gamma_{01}}{\sqrt{\tau_{00} + \sigma^2}}$ and ρ is the intraclass correlation (ICC), $\rho = \frac{\tau_{00}}{\tau_{00} + \sigma^2}$, or the proportion of between-cluster variance within a treatment condition relative to the total variance within a treatment condition.

Recall that the power increases as the noncentrality parameter increases. Eq. (16) demonstrates that power increases as the treatment effect (δ) increases and the sample size increases, and the ICC (ρ) decreases. As noted earlier, the magnitude of the treatment effect is a function of the intervention and hence not typically under the control of the researcher. The ICC is a function of the clusters. That is, the more homogenous the clusters, schools for example, the smaller the ICC. Therefore, the researcher may have some control in reducing the ICC during the sampling stage of the study. However, the sample size is still the parameter that the researcher can influence the most. It is important to note that in a two-level CRT, increasing the total number of clusters (J) has a much stronger effect on the power to detect the main treatment effect than increasing the number of individuals per cluster (n).

Model with a cluster-level covariate

Similar to the case of an individual-level RT, it is common to include covariates to increase the precision of the estimated treatment effect (Bloom et al., 2007). In a two-level CRT, cluster-level covariates, such as school mean achievement scores are frequently incorporated in impact studies because they are more readily available and less costly to collect compared to the data for individual-level covariates. In addition, they explain the between-cluster variance and thus drive down the ICC, which increases the power to detect the treatment effect, holding everything else constant. Hence, we limit our discussion to the case of cluster-level covariates.

The level-1 model is the same as the level-1 model without covariates. The level-2, or the cluster-level model is

$$\beta_{0j} = \gamma_{00} + \gamma_{01}T_j + \gamma_{02}W_j + r_{0j} \quad r_{0j} \sim N(0, \tau_{00|W}) \quad (17)$$

where W_j is the cluster-level covariate and γ_{02} is the effect associated with the covariate. The proportion of between-cluster variance within a treatment condition explained by the covariate is $R^2_{W|T} = 1 - \frac{\tau_{00|W}}{\tau_{00}}$.

Under the alternative hypothesis, the F -statistic follows a non-central F -distribution with 1 numerator and $J - 3$ denominator degrees of freedom. Note that the inclusion of a covariate reduces the degrees of freedom by 1. The standardized version of the non-centrality parameter is:

$$\lambda = \frac{JP(1-P)\delta^2}{\left[(1 - R^2_{W|T})\rho + (1 - \rho)/n \right]} \quad (18)$$

Note that the difference between Eq. (18) and the non-centrality parameter for the model without covariates (Eq. 16) is the factor $(1 - R^2_{W|T})$, which reduces the between-cluster variance within a treatment condition. However, since a cluster-level covariate is at level-2, it does not reduce the within-cluster variance. The more variance explained by the cluster-level covariate, the greater the power, holding everything else constant.

The proportion of variance between-clusters within a treatment condition (ICC) and the proportion of variance explained by a cluster-level covariate ($R^2_{W|T}$) are referred to as the design parameters for conducting a power analysis. These design parameters are context-specific and depend on the specific outcome, sample, nesting structure, etc. Empirical estimates of these design parameters for some outcomes, such as student achievement outcomes, are widely available in the literature (Hedges and Hedberg, 2007; Hedges et al., 2012; Kelcey and Shen, 2016; Spybrook et al., 2016a,b). The literature generally suggests the school-level ICCs, such that involved in the power calculations for two-level CRTs where schools are at level-2, are in the range of 0.14–0.26 for student mathematics and reading achievement outcomes (Hedges and Hedberg, 2007) and 0.17–0.31 for student science achievement outcomes (Spybrook et al., 2016a,b). Similarly, studies of teacher development that draw on two-level CRTs where teachers are nested within schools 2 suggest that ICCs are in the range of 0.16–0.35 for mathematics knowledge for teaching and 0.08–0.24 for reading knowledge for teaching (Kelcey and Phelps, 2013a,b). The school-level R^2 values associated with achievement pretest covariates are 0.71–0.80 for student mathematics, reading, and science achievement outcomes (Hedges and Hedberg, 2007; Spybrook et al., 2016a,b). These design parameters are pertinent in the accuracy of power calculation for CRTs. In the event the empirical estimates are not available for a particular outcome or context, a small pilot study in similar schools with a similar outcome may be useful for generating estimates of the design parameters.

Power calculation for two-level CRTs

The two approaches for conducting power calculation for individual-level RTs also apply to CRTs. Suppose a research team assigns the new reading program to schools, such that half of the schools receive the intervention and the other half continues with the current program. The team is interested in examining the program's impact on students' reading achievement. Using the sample size approach, the team wants to determine the number of schools the study needs to detect a treatment effect of 0.20 with 50 students per school at power = 0.80. The team assumes that 15% of the variance is between the clusters (i.e., ICC = 0.15). Fig. 3 shows the study needs at least 132 schools based on the model without any covariates (solid line). Suppose the team plans to include the school average reading score from a year prior to implementing the intervention as a level-2 covariate. Further, this covariate explains 80% of the between-cluster variance within a treatment condition. Fig. 3 shows the study only needs approximately 40 schools to achieve a power of 0.80 (dashed line), which is approximately 1/3 of those needed for the model without any covariate.

Similarly, the research team could use the effect size approach for power analysis. Suppose the same the research team has a limited budget and they could only recruit 50 schools and 50 students per school. Fig. 4 demonstrates that the MDES is 0.33 based on the model without any covariates (solid line), which is larger than the 0.20–0.30 effect size that studies in education typically are designed to detect. However, when the school average pretest covariate is included as a cluster-level covariate that explains 80% of the between-cluster variance within a treatment condition, the MDES is 0.18 (dashed line in Fig. 4). This new MDES is below the range of 0.20–0.30, which suggests that the study is sufficiently powered to detect a meaningful treatment effect. This example highlights the importance of cluster-level covariates in reducing the sample sizes needed to sufficiently power a study.

Future directions

As the field is accumulating more knowledge on the main treatment effects of educational interventions, which answers the "what works?" question, researchers are also interested in the capacity of RTs to answer more questions. For example, "for whom?", "under what conditions?", and "how?" questions are quintessential for understanding the applicability of interventions across educational contexts and the underlying mechanisms the interventions work to improve student achievement. Researchers often rely on moderator and mediator analyses for answering these questions. As such, more researchers are planning studies and conducting power analyses for main, moderator, and mediator effects (Spybrook et al., 2020).

Moderator effects represent differential treatment effects. For example, one may ask, does the treatment have a differential effect based on gender or pretest score? From a modeling perspective, they are represented by an interaction term between the moderator

Fig. 3 Power versus total number of individuals for CRTs based on the model without covariates (*solid line*) and the model with a covariate that explains 80% of the between-cluster variance within a treatment condition (*dashed line*) at $\alpha = 0.05$. The asterisks represent points where power = 0.80. Note: This figure was retrieved from Optimal Design Plus (Raudenbush et al., 2011).

Fig. 4 MDES versus total number of individuals for CRTs based on the model without covariates (*solid line*) and the model with a covariate that explains 80% of the between-cluster variance within a treatment condition (*dashed line*) at $\alpha = 0.05$. The asterisks represent points where $J = 50$. Note: This figure was retrieved from Optimal Design Plus (Raudenbush et al., 2011).

and the treatment. In an individual-level RT, moderators are the individual-level. In a two-level CRT, moderators may be at the individual-level or cluster-level. The literature on calculating power for moderator effects in CRTs is growing (e.g., Bloom, 2005; Jaciw et al., 2016; Spybrook et al., 2016a,b; Dong et al., 2021; Dong et al., 2020) and software is also available for conducting these analyses (PowerUp!-Moderator, (Dong et al., 2017a)).

Mediator effects are key to understanding the mechanisms through which an intervention comes to be effective. For example, the researcher may want to test the extent to which a new science curriculum operates by first increasing students' interest in science such that the increased interest leads to greater science achievement. Interest in science represents the mediator in this example. Similar to moderators, mediators may be at either the individual-level or the cluster-level. Literature for power calculations for mediator effects is also growing, particularly for CRTs (e.g., Kelcey et al., 2020; Kelcey et al., 2019; Kelcey et al., 2017) and software is also available for conducting these analyses (PowerUp!-Mediator, (Dong et al., 2017b)).

However, there are many challenges ahead. One challenge being the moderator and mediator effect sizes studies should aim to detect. Education researchers typically plan CRTs to detect the main treatment effect of 0.20–0.30 SDs (Hill et al., 2008). The same reference effect sizes for planning studies to detect a moderator or mediator effects are in need of further exploration. As more CRTs are incorporating these types of analyses in their designs, we hope to see more evidence of moderation and mediation effects accumulate in the field.

To achieve understanding, researchers use statistical models to posit theoretical relations between variables in an effort to approximate basic mechanisms underlying processes being studied. Statistical models are comprised of two main elements: (1) a deterministic component and (2) a stochastic, or random, component. The former often contains parameters, which are unknown constants that convey information about the effects or associations among the variables. These parameters are estimated using the sample data. The random component of the model are also variables that are assumed to be sampled from a population distribution with known parameters. A multiple linear regression model is an example of a statistical model in which the relation between a single continuous dependent variable, y and the p independent predictors or explanatory variables, $\mathbf{x} = (x_1, \dots, x_p)$ is defined as

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \dots + \beta_p x_p + e \quad (1)$$

In Eq. (1), $\beta_1, \dots, \beta_p$ are parameters to be estimated and capture the effect of each corresponding x on y . The unobserved random variable, e , in Eq. (1) is the residual or error that captures all other variables that might influence y other than the predictors, $\mathbf{x}$. In other words, it represents all the variation in y that is not explained by $\mathbf{x}$. And because e is a random variable, it carries with it a distributional assumption in the population—often assumed to be a normal distribution.

Using the sample data, the process of estimating the parameters of a statistical model is called *fitting the model*. From a frequentist perspective, many methods exist to estimate parameters of a model such as least squares, method of moments, and maximum likelihood (see, e.g., Lehmann and Casella, 1998, for a comprehensive overview regarding the derivation of several estimators and discussion highlighting their statistical properties). Another popular approach is Bayesian estimation. This approach differs both philosophically and mechanically from frequentist estimation methods. This entry provides an overview of the basic tenets of these approaches for point estimation and how variability of these estimates is defined.

Least squares estimation

A popular method of estimating parameters of a statistical model with a single dependent variable is least squares (LS) estimation (see, e.g., Weisberg, 2014). This approach is based on deriving parameter estimates that minimizes the sum of squared residuals or errors. A general model can be specified for sample size n as

$$y_i = f(\mathbf{x}_i, \boldsymbol{\theta}) + e_i, \quad i = 1, \dots, n \quad (2)$$

where y_i is the dependent variable, $\boldsymbol{\theta}$ is a vector comprised of parameters to be estimated, $f(\mathbf{x}_i, \boldsymbol{\theta})$ is some function of $\boldsymbol{\theta}$ and known values on independent variables $\mathbf{x}_i$, and e_i is the residual. By rearranging the terms in Eq. (2), the residuals can be expressed as $e_i = y_i - f(\mathbf{x}_i, \boldsymbol{\theta})$. That is, residuals are defined as the difference between the outcome, y_i , and the function value, $f(\mathbf{x}_i, \boldsymbol{\theta})$. The LSs solution, $\hat{\boldsymbol{\theta}}$, are estimates of the parameters that minimize the residual sum of squares (RSS)

$$\text{RSS} = \sum_{i=1}^n [y_i - f(\mathbf{x}_i, \hat{\boldsymbol{\theta}})]^2 \quad (3)$$

Fig. 1 Residuals, $\hat{e} = y - \hat{y}$, shown as solid vertical lines for 6 hypothetical bivariate data.

Under the principle of least squares, there is only one unique solution, $\hat{\theta}$ for which RSS is a minimum. **Fig. 1** shows the residuals (solid lines), the discrepancies between y_i and the fitted value, $\hat{y}_i = f(x_i, \hat{\theta})$ at the corresponding value of x_i across all i for six hypothetical data points.

Fig. 2 shows the least squares principle where the residuals are literally “squared” and the total area of those squares when summed, is a minimum. **Fig. 3** shows the same calculation but using $\hat{y} = \bar{y}$ as the best fitting line.

For the ubiquitous linear model (Searle and Gruber, 2016) of Eq. (1), the expression in Eq. (2) can be written in matrix notation familiarly as

$$y = X\theta + e \quad (4)$$

where X is a design matrix whose columns are the independent variables (predictors) in the model augmented with a column of ones while the rows of X represent the n cases in the sample. The predictors can be continuous (e.g., age, height) and can take on an infinite number of possible values or the predictors can be categorical (e.g., gender, ethnicity) taking on a finite, discrete number of values.

The *ordinary least squares* (OLS) solution for $\hat{\theta}$ is solved by determining the parameter estimates that minimize the sum of squared residuals. In matrix notation, this sum can be computed as follows:

$$RSS(\theta) = (y - X\theta)'(y - X\theta) \quad (5)$$

Fig. 2 Schematic of the least squares principle. The residual sum of squares for the OLS best fitting regression line is a minimum.

Fig. 3 Residual sum of squares where $\hat{y} = \hat{\beta}_0$, the mean of y , is the best fitting regression line.

where the prime symbol (') superscript denotes the transpose operator. The minimum of RSS can be computed by multiplying out the right-hand side of Eq. (5)

$$\text{RSS}(\theta) = \mathbf{y}'\mathbf{y} - 2\mathbf{y}'\mathbf{X}\theta + \theta'\mathbf{X}'\mathbf{X}\theta$$

and taking the differential of RSS with respect to θ , setting this expression equal to zero, and solving for θ . The OLS estimates from the normal equations are

$$\frac{\partial \text{RSS}(\theta)}{\partial \theta} = \mathbf{y}'\mathbf{y} - 2\mathbf{y}'\mathbf{X}\theta + \theta'\mathbf{X}'\mathbf{X}\theta$$

$$0 = -2\mathbf{y}'\mathbf{X} + 2\mathbf{X}'\mathbf{X}\theta$$

$$\hat{\theta} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y} \quad (6)$$

provided that the inverse, $(\mathbf{X}'\mathbf{X})^{-1}$, in Eq. (6) exists. The mean square error (MSE), $\hat{\sigma}^2$, can also be expressed in matrix notation as

$$\text{MSE} = \hat{\sigma}^2 = \frac{\mathbf{y}'[\mathbf{I} - \mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}']\mathbf{y}}{n - p - 1} \quad (7)$$

where n is the sample size, and p is the number of predictors in the model. Other statistical components of the linear model such as the sum of squares decomposition in analysis of variance (ANOVA) for comparing group mean differences and numeric quantities such as R^2 can also be expressed in matrix notation (see, e.g., Kutner et al., 2005).

Standard errors. The vast majority of linear models are estimated via OLS. A point estimate of a parameter computed from fitting a linear model to the data presents our best guess of the unknown quantity in the population. A point estimate or confidence interval is at the heart of testing hypotheses about these coefficients and drawing statistical inferences. The other main ingredient to facilitate the testing of hypotheses of model parameters is the estimate's *standard error*. Variances of and covariances among the $p+1$ parameter estimates (including an intercept) capture the precision of these estimates and are computed using the residual variance defined in Eq. (7)

$$\text{var}(\hat{\theta}) = \hat{\sigma}^2(\mathbf{X}'\mathbf{X})^{-1}$$

Standard errors are then obtained by taking the square root of the variance components which are the values on the diagonal of this $(p+1) \times (p+1)$ matrix.

$$\text{SE}(\hat{\theta})_{kk} = \sqrt{\text{var}(\hat{\theta})_{kk}} \quad \text{for } k = 1, 2, \dots, p+1$$

These standard errors can then be used to test hypotheses regarding the estimates, often in the form of a t -test, as well as to derive confidence intervals about corresponding population parameters. For a given significance level, α , (i.e., $\alpha = 0.05$)

$$t = \frac{\hat{\theta}}{\text{SE}(\hat{\theta})} \quad \hat{\theta} - t_{(1-\alpha/2)} \text{SE}(\hat{\theta}) \leq \theta \leq \hat{\theta} + t_{(1-\alpha/2)} \text{SE}(\hat{\theta})$$

where $t(1-\alpha/2)$ is the critical value from the appropriate t -distribution characterized by degrees of freedom (df) at the $100 \times (1-\alpha/2)$ percentile point—the boundary value separating the rejection and acceptance regions.

Generalized least squares

Assumptions of the linear model described in Eq. (4) include independence of observations and homogeneity of variance. That is the conditional variance of the residuals is the same regardless of the values of the independent variables associated with it. If the residuals are correlated or do not have equal conditional variance or both, then the linear model can be fitted to the data using *generalized least squares* (GLS) estimator. Parameters estimated using GLS can be calculated analytically

$$\hat{\theta} = (\mathbf{X}'\mathbf{\Sigma}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{\Sigma}^{-1}\mathbf{y} \quad (8)$$

where $\mathbf{\Sigma}$ is the variance-covariance matrix among the residuals with known elements given $\mathbf{X}$ with rows and columns equal to the number of observations, n . The diagonal elements of $\mathbf{\Sigma}$ are the variances of the residuals across cases and the off-diagonal elements are the covariances between the corresponding pair of residuals. When the covariance matrix $\mathbf{\Sigma}$ is diagonal (i.e., the residuals are uncorrelated), the GLS estimator is referred to as the *weighted least squares* (WLS) estimator.

The GLS structure allows for heteroscedastic patterns in the residuals. A common type of heteroscedasticity is an increasing spread (i.e., fanning) of residuals around the expected mean function. A linear model weights each observation equally when estimating model parameters with OLS. This strategy is fine as long as data are equally clustered around the fitted function across the values of the independent variables. Observations that deviate from this data cluster can have an undue influence on the parameter estimates themselves, and thus, where the fitted function is located. GLS estimation allows for differential weighting of observations through the inclusion of $\mathbf{\Sigma}$ with known elements. These weights are proportional to the reciprocal of the variance of the responses for each case. In practice, this weight matrix is almost never known a priori and must be estimated (i.e., $\hat{\mathbf{\Sigma}}$, which can be particularly challenging to compute for large datasets. The estimator that is obtained

$$\hat{\theta} = (\mathbf{X}'\hat{\mathbf{\Sigma}}^{-1}\mathbf{X})^{-1}\mathbf{X}'\hat{\mathbf{\Sigma}}^{-1}\mathbf{y} \quad (9)$$

is called the *feasible generalized least squares* estimator. There is no universal method for estimating the elements in $\hat{\mathbf{\Sigma}}$, although *iteratively reweighted least squares* has been suggested (see, e.g., Ruppert and Carroll, 1998). Most procedures typically use the residuals from fitting the model to data using OLS as a first-step. How the problem is approached depends on the specific application and on additional assumptions that may be made about the process generating the errors of the model (i.e., moving average process). Note, that if $\mathbf{\Sigma} = \mathbf{I}_n$, where $\mathbf{I}_n$ is an $n \times n$ identity matrix, then the GLS estimator reverts back to the OLS estimator.

Nonlinear least squares

Nonlinear regression models (Bates and Watts, 1988; Seber and Wild, 2003) represent a broad class in which the behavior between the dependent and independent variable is best captured and summarized by a nonlinear function—a function that has at least one parameter that enters the function in a nonlinear fashion (i.e., exponential, logistic, or Michaelis-Menten). Nonlinear functions tend to be used either when they are grounded in theory or to build known curvilinear behavior into a model. Some phenomena like growth, for example, exhibit asymptotic or leveling off behavior. Learning a task has this same type of gradual behavior both at the beginning of the learning process and toward mastery. For the former, an exponential function or a variant of Michaelis-Menten or hyperbolic function (see, e.g., Thurstone, 1919) may be useful to model data with this asymptotic behavior while a logistic function conforms to relational characteristics of learning. Even when a linear approximation works well, a nonlinear model may still be used to retain a clear interpretation of the parameters.

If y is not a linear function of θ in Eq. (2), then the least squares solution (see Eqs. (6) and (8)) can generally not be derived analytically and iterative methods, like Gauss-Newton or Newton-Raphson (see, e.g., Seber and Wild, 2003, for a complete description), must be employed to estimate model parameters. This leads to an estimation method called *nonlinear least squares*. The idea is exactly the same as for linear models—find parameter estimates of the nonlinear function that minimize the sum of the squared residuals.

Maximum likelihood estimation

Estimating model parameters based on the least squares criterion—minimizing the sum of squared residuals—remains a popular technique for statistical methods falling under the *general linear model*. These include multiple linear regression, ANOVA, and their many variants. However, least squares is limited as it can only be used with certain models and sampling designs (i.e., simple random sampling from the population, independence of observations). In practice, a more flexible estimation approach such as maximum likelihood (ML) is used. ML estimation involves defining a likelihood function indicating how likely the observed sample data are as a function of possible parameter values of a statistical model. Thus, maximizing the likelihood function

Fig. 4 Three candidate normal distributions with means at $\mu = 7$, $\mu = 10$, and $\mu = 15$ all with variance equal to 1. A dotplot of the hypothetical data is superimposed below the normal distributions.

determines the parameters that are most likely to have produced the observed data given that the data came from a particular distribution. There are generally three steps in ML estimation:

1. define the distributional assumption on which the statistical model is based,
2. construct the likelihood function—the joint density of the observations conditional on the parameters, and
3. maximize the likelihood function with respect to the parameters.

The basic methodology for ML estimation for a single parameter will be illustrated using a hypothetical data from a normal distribution. Assume that the following ten scores were sampled from a normal distribution:

$$8, 8, 9, 9, 10, 10, 10, 11, 12, 13$$

where it is known that the variance is $\sigma^2 = 1$. The mean of this distribution is unknown, however, and could take on any real value. What value of μ is most reasonable in light of the fact that (1) the population from which the sample was drawn is $y \sim N(\mu, 1)$, and (2) these particular ten observations have been obtained?

To illustrate the idea behind ML estimation, consider the three different normal distributions in Fig. 4—each is a potential candidate to have produced these data. On the bottom of Fig. 4, the ten data values are graphed as a dot plot. Above the data are three representative normal distributions which differ in terms of μ , but whose variance is $\sigma^2 = 1$. Of course, there are many other possible normal distributions, but these three illustrate the kind of match of distribution to data we want.

The likelihood function is essentially a measure of closeness that describes numerically how well the data conform to the distribution for various values of the parameter. The way this is done operationally is to compute the product of function values evaluated at each data point given particular values of the parameters. The parameter values that give the best performance in terms of similarity of the distribution to the data—maximizing the likelihood function—are called the maximum likelihood estimates (MLEs) of the parameters.

To carry on with our example, the likelihood function is constructed using the normal distribution with mean, μ and variance, $\sigma^2 = 1$

$$f(y_i | \mu, \sigma^2 = 1) = \frac{1}{\sqrt{2\pi}} \exp \left\{ -\frac{1}{2}(y_i - \mu)^2 \right\} \quad (10)$$

Then the likelihood functions for our three candidate values of μ evaluated at the 10 data points are

$$\begin{aligned} L(\mu = 7 | y, \sigma^2 = 1) &= \prod_{i=1}^{10} f(y_i | \mu = 7, \sigma^2 = 1) \\ &= f(y_1 = 8 | \mu = 7, \sigma^2 = 1) \times \cdots \times f(y_{10} = 13 | \mu = 7, \sigma^2 = 1) \\ &= 0.24197 \times \cdots \times 0.0000061 \approx 1.796037E - 29 \end{aligned}$$

$$\begin{aligned}
 L(\mu = 10 | \mathbf{y}, \sigma^2 = 1) &= \prod_{i=1}^{10} f(y_i | \mu = 10, \sigma^2 = 1) \\
 &= f(y_1 = 8 | \mu = 10, \sigma^2 = 1) \times \cdots \times f(y_{10} = 13 | \mu = 10, \sigma^2 = 1) \\
 &= 0.05399 \times \cdots \times 0.00443 \approx 6.274323\text{E} - 10 \\
 \\
 L(\mu = 15 | \mathbf{y}, \sigma^2 = 1) &= \prod_{i=1}^{10} f(y_i | \mu = 15, \sigma^2 = 1) \\
 &= f(y_1 = 8 | \mu = 15, \sigma^2 = 1) \times \cdots \times f(y_{10} = 13 | \mu = 15, \sigma^2 = 1) \\
 &= 9e - 12 \times \cdots \times 0.0539 \approx 3.241579\text{E} - 64
 \end{aligned}$$

Because $L(\mu = 10 | \mathbf{y}, \sigma^2 = 1)$ is greater than $L(\mu = 7 | \mathbf{y}, \sigma^2 = 1)$ and $L(\mu = 15 | \mathbf{y}, \sigma^2 = 1)$, $\mu = 10$ explains the data better than the other two possibilities. For this reason it may be said that with these alternatives, the MLE is $\hat{\mu} = 10$. For the data $\mathbf{y} = (8, 8, 9, 9, 10, 10, 10, 11, 12, 13)$ the likelihood function across values of μ is shown in Fig. 5. The maximum occurs at $\hat{\mu} = 10$.

Note that in the previous hypothetical example the value of likelihood function is a very, very small number. For a variety of reasons, but especially true for computing MLEs using statistical software, the loglikelihood function is used instead of the likelihood function. The logarithm function is monotonically increasing and order-preserving, and thus, maximization of the logarithm of a function is equivalent to maximization of the function itself. With the logarithmic transformation, the very small numbers computed using the likelihood function will be converted to large negative numbers—ameliorating the analytic computations as well as underflow of the computer's numerical precision.

In general, there are more than three alternative values for a parameter—as was the case in the hypothetical example above. For instance, μ could take on any real numbered value (i.e., $\mu \in \mathbb{R}$). To determine the MLE, one evaluates the loglikelihood,

$$l(\mu | \mathbf{y}, \sigma^2 = 1) = \log L(\mu | \mathbf{y}, \sigma^2 = 1) = -\frac{1}{2} \sum_{i=1}^n (y_i - \mu)^2 \quad (11)$$

taking $\hat{\mu}$ to be the value for which the loglikelihood is largest. This is done algebraically or numerically (i.e., using the computer), not by examining values of the likelihood empirically. The algebraic solution for this single parameter ML problem is based on the fact that the slope of the tangent line (i.e. the first partial derivative of the loglikelihood function) at the maximum is 0 (see Fig. 6).

Fig. 5 Maximum likelihood estimate, $\hat{\mu} = 10$, for the mean of a normal distribution computed using the hypothetical data.

Fig. 6 The slope of the tangent line (— —) evaluated at the parameter estimate that produces a maximum value of the likelihood function, is zero.

Thus, finding the MLE requires taking the first derivative of the loglikelihood in [Eq. \(11\)](#),

$$\frac{\partial}{\partial \mu} l(\mu | y, \sigma^2 = 1) = \sum_{i=1}^n (y_i - \mu)$$

setting the expression equal to zero, and solving for the unknown parameter, μ .

$$0 = \sum_{i=1}^n (y_i - \mu)$$

$$\hat{\mu} = n^{-1} \sum_{i=1}^n y_i = \bar{y}.$$

It may come as no surprise that the ML estimate of μ is the sample mean, $\bar{y}$. Maximum likelihood can also be used to estimate several parameters, $\theta = (\theta_1, \dots, \theta_q)$ simultaneously, with $q > 1$. For example, to estimate the coefficients and residual variance in a multiple linear regression model assuming normality of the residuals. In that case it is necessary to maximize the likelihood with respect to all parameters. This can be done by computing the partial derivatives of the loglikelihood with respect to each parameter and setting each partial derivative equal to zero. It is then necessary to solve a system of equations equal to the number of parameters being estimated.

$$\frac{\partial l(\theta)}{\partial \theta_k} = 0, \quad k = 1, \dots, q$$

Generally speaking, although it is theoretically possible to write out, differentiate the loglikelihood function with respect to the various model parameters and solve the resultant system of equations, this becomes increasingly tedious even for the relatively simple models with few parameters. With the aid of computers, iterative numerical methods are used instead to solve the system of equations.

Maximizing the loglikelihood function

Several iterative methods have been developed to maximize loglikelihood functions with multiple parameters. These methods are generally categorized into derivative-free methods and methods based on using first- and/or second-derivatives of the loglikelihood function with respect to the parameters. Derivative-free methods include the Nelder-Mead algorithm ([Nelder and Mead, 1965](#)) which uses function values of the loglikelihood and a series of pre-determined steps to explore the loglikelihood surface in search for a maximum. Another such derivative-free method is simulated annealing ([Kirkpatrick et al., 1983](#)). Simulated annealing is a stochastic local search technique that approximates the global maximum of the loglikelihood function through an iterative progression in which an initial solution is repeatedly improved by making small, local alterations until no such modification yields a better solution ([Fouskakis and Draper, 2002](#)).

Newton-Raphson (N-R) or one of its variants is perhaps the most common method for facilitating ML estimation. This method uses first- and second-derivatives of the loglikelihood function and initial values (educated guesses) of the parameters must be provided by the analyst to get the algorithm started. At the $w + 1$ iteration of the algorithm, N-R updates parameters, θ as

$$\theta^{w+1} = \theta^w - \mathbf{H}(\theta^w)^{-1} \mathbf{g}(\theta^w)$$

where θ^w are the current values of the parameters, $\mathbf{g}(\theta^w)$ is the gradient (or score) vector—that is the first derivative of $l(\theta)$ with respect to each parameter in θ , whereas $\mathbf{H}(\theta^w)$ is the *Hessian* matrix—that is the matrix of second partial derivatives of $l(\theta)$. The observed information matrix from which standard errors for the parameters are obtained is the negative of the Hessian matrix and is often denoted as $\mathbf{J}(\theta^w) = -\mathbf{H}(\theta^w)$. A common variant of the N-R algorithm is the Fisher-scoring algorithm, which at each iteration, updates parameters using expected, not observed, information, $\mathbf{I}(\theta^w) = -E[\mathbf{H}(\theta^w)]$. These two approaches of approximating the information matrix from which standard errors are extracted are asymptotically (i.e., in large samples) equivalent and in practice, either could be used.

One of the reasons for its popularity is that it is said to be quadratically (rapidly) convergent in the neighborhood of the solution. This is an advantage of the N-R method but also one of its potential liabilities. If in fact, the initial parameter estimates are far away from the maximum, there is no guarantee that the N-R algorithm will converge to a maximum at all. Typically, the N-R algorithm stops and claims that a maximum has been reached when some convergence criterion such as when the set of partial derivatives of the loglikelihood function are close to zero, is met. Though it is generally possible for the N-R algorithm to find a local maximum of the loglikelihood function, it is not guaranteed that this also corresponds to the global maximum of the likelihood surface. When there are multiple local maxima (i.e., for increasingly complex statistical models) a critical analytic decision point is that of the choice of the starting values for the algorithm. Approaches like the method of moments are frequently used to obtain reasonable starting values when user-defined values or the default settings in statistical software are inadequate.

Hypothesis testing and confidence intervals for MLEs

In addition to deriving parameter estimates, it is also important to determine the accuracy of the estimates. Like least squares estimation, the standard errors of the MLEs are used for this purpose to facilitate hypothesis testing and create confidence intervals of population parameters. Standard errors are obtained from using either the expected or observed information matrix previously discussed. Again, adding to its popularity as a general optimization scheme for ML estimation, the N-R algorithm uses the observed information matrix. This is computed as the negative of the Hessian matrix, second partial derivatives of the loglikelihood, and is obtained as a byproduct of the N-R algorithm. As a result of likelihood asymptotic theory (see, e.g., [Lehmann and Casella, 1998](#)), the variance-covariance matrix of the MLEs of the parameter estimates at convergence of the algorithm, Σ , is simply the inverse of the observed information matrix. That is, $\Sigma(\hat{\theta}) = \mathbf{J}(\hat{\theta})^{-1}$. The diagonal elements will be the variances of the MLEs, and the off-diagonal elements will be the covariances between them. These are needed to test hypotheses based on linear functions of the parameters.

Model comparisons

Maximum likelihood estimation also facilitates the testing of two competing, nested models via the likelihood ratio test (LRT). The LRT assesses the goodness-of-fit of two statistical models based on the ratio of their likelihood function values (or difference of their loglikelihood function values), specifically one calculated by maximizing over the entire parameter space and the other computed after imposing some constraint(s). In a likelihood ratio test the loglikelihood value obtained under two alternative hypotheses are compared. In the model under the null hypothesis termed the *reduced* model, one or more of the parameters that are maximized in the alternative hypothesis are assumed fixed to a value (i.e., zero) or set equal to other parameters in the competing model. For example, residual variances in two linear regression models are set equal to one another. The model under the alternative hypothesis is termed the *full* model because maximum likelihood estimates are derived for all parameters. Often, the likelihood ratio test statistic is expressed as a difference between the loglikelihood values

$$\lambda_{LR} = -2 \left[l(\hat{\theta}_{\text{reduced}}) - l(\hat{\theta}_{\text{full}}) \right]$$

Under the assumption that the null hypothesis is correct, this difference will be asymptotically distributed as χ^2 on degrees of freedom equal to the difference in the number of parameters that are estimated in the two models. Large values of λ_{LR} lead to rejecting the reduced model (i.e., the null hypothesis) in favor of the full model while small values of λ_{LR} lead to a failure to reject the null hypothesis. In other words, small λ_{LR} values lead to p -values greater than the nominal 0.05 suggesting that the reduced model with fewer parameters does not fit appreciably worse than the full model. The LRT requires that the models be nested (i.e., the full model can be transformed into the reduced model by imposing constraints on the parameters of the full model). Comparing two non-nested models can be accomplished using popular information criteria such as AIC [Akaike \(1974\)](#) or BIC [Schwarz \(1978\)](#), which are formulated using the loglikelihood.

Properties of frequentist estimators

Point estimators and interval estimators are two primary types of estimators in statistics. A point estimator is a single value of a statistic from the sample data representing an estimate of its corresponding unknown parameter in the population. It is a random variable and therefore varies from sample to sample. A *confidence interval* is an interval estimator from a frequentist perspective which uses the sample data to compute a range of values that is likely to include population parameters with a certain degree of confidence. This is often expressed as a percentage (i.e., 95% confidence interval). The endpoints of the intervals are referred to as the upper and lower confidence limits.

For many classes of statistical models there are a number of estimation procedures that can be called upon when fitting models—usually specified as an option within the particular statistical software. Frequently, different procedures solve the same estimation problem. That is, the parameter estimates (and corresponding standard errors) produced by these seemingly disparate approaches, are identical. OLS and ML estimation approaches will arrive at the same parameter estimates for a multiple linear regression model, for example, if the errors are assumed to come from a normal distribution. However, this is an exception and not the rule. Parameter estimates obtained by different estimation methods (i.e., estimators) typically have different statistical properties (i.e., distributional assumptions, variance, bias). The choice between competing estimation principles is often made on the basis of these properties. There are three desirable properties every good estimator should possess: (1) unbiasedness, (2) consistency, and (3) efficiency.

A point estimator, $\hat{\theta}$, is an unbiased estimator of the true population parameter, θ , if its expected value is equal to the population parameter (i.e., $E[\hat{\theta}] - \theta = 0$; for finite sample size, n). Put another way, the unbiasedness property of an estimator implies that the average of an estimated value computed from many samples approaches the true, but unknown, population parameter. A non-zero difference indicates bias.

An estimator, $\hat{\theta}$, of the population parameter, θ , is said to be *consistent* if its sampling distribution becomes more concentrated around the true value of the population parameter as the sample size increases (i.e., $n \rightarrow \infty$). Intuitively, a consistent estimator tends to get closer to the parameter it is estimating as the sample size increases.

The most *efficient* point estimator is the one with the smallest variance of all the unbiased and consistent estimators considered with finite sample sizes. The variance measures the level of dispersion of the estimate from sample-to-sample. In short, if two unbiased estimators $\hat{\theta}_1$ and $\hat{\theta}_2$ are considered, the estimator with a smaller variance—more precision—is preferred.

Choosing an estimator (i.e., maximum likelihood) for a particular application may seem rather challenging, but the reality is much less intimidating. Many classes of models typically have a default estimator that capitalizes on the statistical properties previously mentioned. For example, the default estimation approach for the broad class of generalized linear models (e.g., logistic regression) in many statistical software programs is maximum likelihood whereas ordinary least squares is the default estimation scheme for linear regression models. The choice is not as clear for models accommodating multiple categorical, dependent variables (e.g., structural equation models, generalized linear mixed effects models) and a final decision is often based on ease of implementation, computational effort, in addition to sound statistical properties. Even if the default estimator is ultimately chosen, it is important to know what trade-offs exist in the context of your data and statistical model.

Bayesian estimation

For frequentist estimation approaches like least squares and maximum likelihood, data are viewed as random while population parameters such as linear regression coefficients are treated as unknown, but fixed quantities. The implication is that a single population value can be uncovered for each unknown parameter. The primary goal in estimating such quantities is to facilitate statistical inference—that is to construct confidence intervals around the sample point estimates and to carry out hypothesis tests based on assuming an appropriate statistical null hypothesis in hopes that the data will provide sufficient evidence against it. It may be interest, for example, to determine which independent variables are the best predictors of high school dropout using a logistic regression model. In such a model, testing whether individual regression parameters are zero in the population is of interest as is constructing confidence intervals to convey ranges of values that these parameters are likely to be with a given probability.

In the Bayesian paradigm, unknown population parameters are treated as random variables that follow a certain distribution and the data, once obtained, are viewed as fixed. Prior knowledge or beliefs about the possible shape, location, and variability of this distribution are modeled by specifying a prior distribution on the parameters that will be updated by the data through the likelihood function to form a posterior distribution for the parameters. This relation between prior distribution of a parameter θ , the distribution of the likelihood and the posterior distribution is displayed in Fig. 7.

The rationale behind Bayesian estimation is grounded in Bayes's theorem, which states

$$p(\theta|y) = \frac{p(y|\theta)p(\theta)}{p(y)} \quad (12)$$

Fig. 7 Prior, likelihood, and posterior distributions for parameter θ .

The numerator of the expression on the right-hand side of Eq. (12) represents the conditional probability distribution, $p(y|\theta)$ of the data y given model parameters, θ . For fixed, known data this distribution is the likelihood function and is multiplied by the marginal distribution, $p(\theta)$ which is referred to as *prior probability distribution* of model parameters. The denominator in Eq. (12) is $p(y) = \int p(y|\theta)p(\theta)d\theta$ and represents the marginal probability distribution of the observed data in the case of continuous parameters or $\sum_{\theta} p(y|\theta)p(\theta)$ for discrete parameters with the sum being taken over all possible values of θ . In general, direct computation of the integral (or sum) in the denominator of Eq. (12) is difficult to carry out analytically—even for simple models. Yet, this barrier can be bypassed by noticing that $p(y)$ does not vary as a function of θ and consequently, is often dropped from the expression. Bayes's theorem is frequently represented as a proportional relation (Carlin and Thomas, 2009),

$$p(\theta|y) \propto p(y|\theta)p(\theta) \quad (13)$$

The expression on the left-hand side of Eq. (13), $p(\theta|y)$, is referred to as the posterior distribution, which captures what is believed about the parameters after having integrated the information contained in the data. According to Levy (2016), the posterior distribution is the “solution” or “answer” from a Bayesian analysis. In other words, inference from a Bayesian analysis is focused on constructing and sampling from the posterior distribution, and as a distribution, it is often summarized and communicated with typical graphics and summary statistics. For example, histograms or density plots may be used to visualize patterns of symmetry or asymmetry. The mean, median or mode of the posterior distribution may be used as a measure of central tendency while the standard deviation of the posterior could be used as a measure of dispersion or variability. Other quantities of interest that summarize the posterior include Bayesian posterior p values and Bayes Factors (BFs) for hypothesis testing as well as constructing a *credibility interval* (i.e., Bayesian “confidence interval”) which indicates a region of the distribution with a given probability. The 90% highest posterior density (HPD) credibility interval of θ , for instance, is the interval for which the probability that θ is inside that interval in the posterior distribution is 0.90. The HPD credibility interval is constructed in such a way that no value outside the interval has a higher posterior density than any value inside the interval.

The Bayesian approach to estimation is an attractive alternative to frequentist methods like maximum likelihood because Bayesian statistics do not rely on large sample theory (i.e., central limit theorem) to make valid inferences and therefore, may produce reasonable results even with small to moderate sample sizes. This is particularly true when background knowledge about the model parameters is available. Generally, the more information a researcher can specify before observing the data, the smaller the sample size required to obtain the same certainty compared to an analysis that incorporates no prior knowledge. The Bayesian framework allows the researcher to interact in estimating model parameters in a way that he or she is unable to do in the frequentist estimation paradigm. This type of interaction is done through the specification of prior distributions of model parameters.

Prior distributions

Mechanically, incorporating prior distributions of model parameters into the estimation process distinguishes the Bayesian approach to estimation from frequentist methods. Prior distributions are probabilistic in nature that reflect an investigator's previous beliefs and knowledge of certainty about these parameters, such as their location or scale. These beliefs are specific to the investigator (i.e., two investigators may assert dissimilar beliefs about characteristics of a distribution regarding the same parameter). Great uncertainty in model parameter values is quantified by specifying a diffuse or non-informative prior distribution that is characterized by large dispersion. Examples of diffuse priors might include a uniform distribution over the real number line or a normal distribution with an enormous variance. Greater certainty about model parameter values translates into specifying so-called informative or subjective prior distributions in which the strength of one's belief is inversely related to the variability of the distribution. In fact, there is a continuum of informativeness that can be built into estimating parameters with a Bayesian framework. Fig. 8 shows three different normal distributions labeled as non-informative, weakly informative and informative to provide some visual context to what these descriptors mean. Note that the location of each of the normal distributions is centered at 2 (i.e., unstandardized regression coefficient) but have varying degrees of variability.

The combination of large sample size and diffuse prior distributions yield results that appear similar to those from a frequentist analysis. The posterior mean tends to be close to the MLE, the posterior standard deviation appears to be close to the standard error, and the limits of a posterior credibility interval tends to be close to a confidence interval with the same coverage. In large samples, the likelihood, not the prior distribution, seems to dominate the distributional characteristics of the posterior. When conducting a Bayesian analysis with small sample sizes, the prior distribution can play a more important role. In practice, prior distributions are often not carefully chosen, and many applied studies using Bayesian analysis rely on default software settings or generic heuristic values. These naive priors (McNeish, 2016) are in contrast to non-informative prior distributions, both of which can actually be quite informative if poorly chosen and when the sample size is small. A sensible justification should be provided for why a particular prior is suitable for a specific parameter. Other characteristics of prior distribution specification such as choosing the functional form of the distribution, conjugate and improper priors, and hyperpriors in a fully Bayesian analysis are more fully discussed by (Levy and Mislevy, 2016; Rupp et al., 2004).

Parameter estimation via Gibbs sampling

In the vast majority of modeling situations in which Bayesian estimation is utilized, a closed-form solution for the posterior does not exist or is analytically intractable. In these cases, inference proceeds by implementing a computational-intensive approach that

Fig. 8 Non-informative (—), weakly informative (— — —), informative (·····) normal prior distributions for an unstandardized regression coefficient located at 2.

approximates the posterior distribution instead. Sampling from the posterior distribution can be obtained via Markov chain Monte Carlo (MCMC) simulation methods. MCMC methods are useful for sampling from high-dimensional multivariate densities by separating these densities into more tractable univariate or smaller dimensional multivariate densities [Lynch \(2007\)](#). That is, MCMC methods, avoids sampling directly from the joint posterior distribution by drawing samples from the full conditional posterior distribution of each parameter conditioned on the data and the most recent value of all other parameters (see, e.g., [Levy and Mislevy, 2016](#)). Popular MCMC algorithms that facilitate estimation of model parameters include the random-walk Metropolis-Hastings algorithm, the “No-U-turn” sampler, an extension of the Hamiltonian Monte Carlo algorithm, and the ubiquitous Gibbs sampler.

The idea behind the Gibbs sampler is to generate a sequence of samples from the joint probability distribution (i.e., the posterior distribution) of two or more random variables by iterating through each variable (or block of variables), drawing a sample from its conditional distribution with the remaining variables fixed to their current values evaluated with the sample data. The sequence of draws is linked, forming a chain, in that the current value in the chain depends on the previous value in the chain. In a Bayesian analysis, the chain is constructed such that it converges to the posterior distribution. In other words, a large enough number of draws in the chain may be considered drawing samples from the posterior distribution. Gibbs sampling is applicable when the joint distribution is not known explicitly or is difficult to sample from directly, but the conditional distribution of each variable (or small set of variables) is known and is easier to sample. To be concrete, suppose a Bayesian analysis was to be performed for a multiple linear regression model with three predictors $y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + e$. The parameters of the model to be estimated are $\theta = (\beta_0, \beta_1, \beta_2, \beta_3, \sigma_e^2)$. The joint distribution of the parameters given the data, $p(\theta|y, x)$ makes up the posterior distribution. The basic idea of Gibbs sampling is to iteratively sample from the conditional distribution $p(\theta_d|y, x, \theta_{-d})$ where θ_{-d} denotes the parameter vector, θ without the parameter d . Then the algorithm proceeds in the following manner over $B(1, \dots, B)$ draws:

Step 1: Provide initial starting values for the parameters, $\theta^{(0)} = (\beta_0^{(0)}, \beta_1^{(0)}, \beta_2^{(0)}, \beta_3^{(0)}, \sigma_e^{2(0)})$

Step 2: Generate draws from the conditional distributions at iteration $b + 1$ as follows:

$$\begin{aligned}\beta_0^{(b+1)} &:= \beta_0^* \sim p(\beta_0^{(b)} | y, x, \beta_1^{(b)}, \beta_2^{(b)}, \beta_3^{(b)}, \sigma_e^{2(b)}) \\ \beta_1^{(b+1)} &:= \beta_1^* \sim p(\beta_1^{(b)} | y, x, \beta_0^{(b+1)}, \beta_2^{(b)}, \beta_3^{(b)}, \sigma_e^{2(b)}) \\ \beta_2^{(b+1)} &:= \beta_2^* \sim p(\beta_2^{(b)} | y, x, \beta_0^{(b+1)}, \beta_1^{(b+1)}, \beta_3^{(b)}, \sigma_e^{2(b)}) \\ \beta_3^{(b+1)} &:= \beta_3^* \sim p(\beta_3^{(b)} | y, x, \beta_0^{(b+1)}, \beta_1^{(b+1)}, \beta_2^{(b+1)}, \sigma_e^{2(b)}) \\ \sigma_e^{2(b+1)} &:= \sigma_e^{2*} \sim p(\sigma_e^{2(b)} | y, x, \beta_0^{(b+1)}, \beta_1^{(b+1)}, \beta_2^{(b+1)}, \beta_3^{(b+1)})\end{aligned}$$

Step 3: Repeat until convergence.

A primary advantage of Gibbs sampling is its simplicity. In contrast to the Metropolis-Hastings algorithm, proposed links (the next draw from the conditional distribution) in the chain are always accepted. The primary disadvantage is that the conditional distributions, like those in the previous example, must be derived for successful implementation. This is a tractable problem when the prior probability distribution $p(\theta_d)$ is conjugate to the posterior distribution. This distinction is more theoretical than practical as most statistical software that conducts Gibbs sampling, as well as other MCMC algorithms, to some extent automates the computational “heavy-lifting,” ameliorating concerns that data analysts or researchers might have.

Lastly, this short introduction to Bayesian estimation did not include any discussion of important computational issues, challenges, and analytic decision points such as assessing convergence, strategies of assigning multiple chains, choosing a burn-in period when sampling, evaluating auto-correlation, assessing data-model fit, and model selection. The interested reader is directed to texts by [Levy and Mislevy, 2016](#) and [Kaplan, 2014](#) for detailed explanation of these, and other, important concepts when taking a Bayesian approach to estimating parameters of a model.

Conclusion

George [Box et al. \(2005\)](#) is often credited with the insightful maxim “While all models are wrong, some are useful” (p. 440). Although many statistical models do not perfectly map onto the complex underlying processes found in educational research studies, they are often useful approximations. These sentiments were nicely captured in the title of [Micceri’s \(1989\)](#) paper, “The unicorn, the normal curve, and other improbable creatures.” The normal curve does not actually occur in nature, but it is a very useful model that adequately summarizes many continuously-scaled variables. Whether these models are good representations of the underlying theoretical mechanism or empirically driven through data exploration, parameters corresponding to interesting facets of the phenomenon summarized by these models will need to be estimated. This model fitting activity is at the heart of *statistical inference*. From both frequentist and Bayesian perspectives, many estimation approaches exist that are regularly used in this process. Although there are many estimators that were not discussed in this entry (i.e., method of moments, iteratively reweighted least squares), omnipresent approaches, ordinary least squares, maximum likelihood, and Bayesian methods via MCMC algorithms, were. Their popularity notwithstanding, OLS, ML, and Bayesian estimators have desirable statistical properties and can be effectively used in a variety of data analytic situations (i.e., nested data structures, longitudinal and cross-sectional designs, increasingly complex models) and across nuanced data conditions (i.e., missing data).

Overview

Missing data analysis has been an active area of research for several decades and is an interdisciplinary subject. Scientific contributions to this area have been published in journals from statistics, biostatistics, survey statistics, and quantitative methods in psychology and education, among others. Missing data analysis is a broad term that is typically used to refer to both statistical aspects of missing data as well as statistical methods that are used when there are missing values in a dataset. Such methods may seek to identify characteristics of missing values, facilitate valid statistical inferences in the context of missing data, or assess the extent to which statistical results are influenced by uncertainty regarding characteristics of missing values. Missing data, missingness, and nonresponse are all terms that describe such missing values.

Statistical approaches used in missing data analysis operate by making assumptions about the underlying reason for missingness, most popularly categorized by the so-called missing-data mechanisms ([Rubin, 1976](#)).

Missing-data mechanisms

Missing-data mechanisms (or, alternatively, missingness mechanisms) describe characteristics of missing values with respect to “the relationship between missingness and the values of variables in the data matrix” ([Little and Rubin, 2002](#)). Missing values can be classified as belonging exclusively to one of the three missing-data mechanisms according to their dependence on the observed values in the dataset, missing values in the dataset, or neither. Formally, this is described through the conditional distribution of missingness, which is given by

$$f_{M|Y}(m_i|y_i, \psi) \quad (1)$$

where y_i is the set of data values for subject i in the complete dataset $Y = (y_{ij})$, ψ are parameters associated with the model of the missingness process, and $M = (m_{ij})$ is a matrix of missing-data indicators with $m_{ij} = 1$ if y_{ij} is missing and $m_{ij} = 0$ if y_{ij} is observed. The missing-data mechanisms describe how this conditional distribution of missingness can or cannot be simplified.

Missing completely at random

Under the Missing Completely At Random (MCAR) mechanism, missingness does not depend on the values of variables in the dataset—neither missing nor observed. This implies that the conditional distribution of missingness can be simplified to (Little and Rubin, 2002)

$$f_{M|Y}(m_i|y_i, \psi) = f_{M|Y}(m_i|\psi) \forall y_i, \psi \quad (2)$$

For example, suppose respondents are given a random subset of items on a survey from a larger item bank such that items are assigned to respondents with equal probability. In such planned missingness designs, the missing responses on those unassigned items for a given participant fall under the MCAR mechanism.

Missing at random

Under the Missing At Random (MAR) mechanism, missingness does not depend on the missing values themselves after the observed values have been conditioned on. That is, the conditional distribution of missingness can be simplified to (Little and Rubin, 2002)

$$f_{M|Y}(m_i|y_i, \psi) = f_{M|Y}(m_i|y_{i(0)}, \psi) \forall y_{i(1)}, \psi \quad (3)$$

where $y_{i(0)}$ denotes the set of observed values for subject i and $y_{i(1)}$ denotes the set of missing values for subject i . For example, suppose respondents are given an educational assessment that consists of two sections. Suppose also that the second section of the assessment is only administered to respondents who score above a certain threshold on the first section. This planned missingness design will create missing responses on the second section for respondents who scored below the chosen threshold. Such missing responses fall under the MAR mechanism.

Missing not at random

Under the Missing Not At Random (MNAR) mechanism, missingness depends on the missing values themselves, even after the observed values are conditioned on. In other words, there is no way to remove the dependency on such missing values statistically with the observed data. The MNAR mechanism can be further subdivided into two subtypes, called focused and diffuse MNAR (Gomer and Yuan, 2021). Missingness under the focused MNAR subtype depends only on the missing values themselves, while missingness under the diffuse MNAR subtype depends on both the missing values and the observed values in the dataset. Historically, the MNAR mechanism has typically been described in words rather than re-expressions of the conditional distribution of missingness, but recent work has provided specific formulations for the MNAR subtypes. For focused MNAR, the conditional distribution of missingness can be simplified to (Gomer and Yuan, 2021)

$$f_{M|Y}(m_i|y_i, \psi) = f_{M|Y}(m_i|y_{i(1)}, \psi) \forall y_{i(0)}, \psi \quad (4)$$

For diffuse MNAR, the conditional distribution of missingness cannot be simplified at all, and instead is given by Gomer and Yuan (2021)

$$f_{M|Y}(m_i|y_{i(0)}, y_{i(1)}, \psi) \forall y_{i(1)}, \psi \quad (5)$$

which is repeated from Eq. (1), in which y_i is replaced with $(y_{i(0)}, y_{i(1)})$.

Remarks on the definitions of missing-data mechanisms

Note that in the definitions of MAR and diffuse MNAR, $y_{i(0)}$ represents the variables that are observed and explicitly used in the formulation of the likelihood function. A survey may contain many items; those that are observed but not used in the formulation of the likelihood function are equivalent to missing values. Also note that the classification of the different missing-data mechanisms is motivated by the need to simplify the likelihood function for statistical modeling, and not just mathematical brevity.

Methods to handle missing values

Methods to handle missing values, or missing-data methods, are statistical approaches that provide either (1) an artificially complete dataset that no longer contains missing values, or (2) facilitate statistical inference even in the presence of missing data. In both cases, the end-goal of missing-data methods is typically to obtain statistical inferences for the analysis model of interest from a dataset that originally contained missing values.

Missing-data methods can also be classified according to the strategies they use to handle missing values, and typically fall under one or more of the following categories: (1) deletion-based procedures, (2) weighting procedures, (3) imputation, and (4) model/distribution-based methods.

Another important distinction is between ad hoc methods and principled methods: ad hoc methods are convenience-based approaches that generally provide a single artificially complete dataset and can only provide valid statistical inferences for certain population parameters in very restrictive conditions. Principled approaches, on the other hand, have better statistical justification and provide valid statistical inferences for parameters of the population distribution or the analysis model of interest under less restrictive settings.

Ad hoc methods

The most commonly used ad hoc approaches fall into one of two categories: (1) deletion-based methods or (2) single imputation.

Deletion-based methods

Listwise deletion, also called complete case analysis, is a deletion-based missing-data method that removes all data values associated with cases or respondents that have missing values. Under this approach, if a participant responds to 20 out of 21 survey items, the entire row of the dataset that corresponds to that participant is deleted—and even the information from the 20 observed items for that participant is lost. This also means that if a dataset contains 20 such nonrespondents out of 100 respondents in total, the sample size after listwise deletion is reduced to 80. The operating assumption of listwise deletion is that missing values are MCAR. Under this assumption, the data from the complete cases can be regarded as a random sample from the population distribution of interest and thus will still yield statistical inferences that are unbiased. However, a potent drawback to this approach is that even when the assumption of MCAR is satisfied, the reduced sample size leads to decreased statistical power. When missingness is instead MAR or MNAR, listwise deletion generally leads to invalid statistical inferences. In many statistical software programs, listwise deletion is used by default when data contain missing values and no other missing-data method is specified.

Pairwise deletion, sometimes referred to as available case analysis, is another deletion-based missing-data method. This approach uses all the observed (i.e., available) values from incomplete cases in the calculation of statistical estimates. In the case of correlations, all pairwise complete observations are used from the variables of interest. Thus, even if a participant has a missing response on item 21 of a survey, her values on the other 20 items are included when calculating those item correlations. The operating assumption of pairwise deletion is that missing values are MCAR. Under this assumption, pairwise deletion provides unbiased estimates for several types of parameters. Pairwise deletion will result in greater statistical power compared to listwise deletion. However, pairwise deletion suffers from problems of comparability: statistical estimates obtained via pairwise deletion may not be based on the same members of the sample and thus are no longer strictly comparable. The overall sample size may also be unclear when covariances are based on different numbers of observations, which can lead to biased test statistics in contexts such as structural equation modeling (Marsh, 1998). Another drawback of pairwise deletion is that it can sometimes result in correlation and covariance matrices that are not positive definite, which is problematic for multivariate statistical analysis (Wothke, 1993).

Single-imputation

Mean substitution, also called unconditional mean imputation or simply mean imputation, is a single-imputation missing-data method that replaces missing values on a variable with the mean calculated from its observed values. This will result in an artificially complete dataset that has the same sample size as the original data. Stated generously, the operating assumption of mean substitution is MCAR—but even under this assumption, mean substitution can only provide unbiased estimates with respect to the mean. This unbiasedness is possible because there is no systematic difference between the missing and observed values under MCAR, so replacing missing values with the mean will not bias the results. However, statistical estimates of other parameters are invalid even under the assumption of MCAR because the variation of the values themselves is reduced while the sample size is artificially inflated (Peugh and Enders, 2004).

Regression imputation, also sometimes called conditional mean imputation, is a single-imputation missing-data method that replaces missing values with their predicted values from a regression model. This model regresses the missing variable on the variables which are completely observed for the given case or respondent, and is often based on the subset of the sample whose values are observed for that particular set of variables. Thus, stated generously, the operating assumption of regression imputation is that missingness is MAR or MCAR. However, as with mean substitution, the variability of values on the missing variable is underrepresented by regression imputation which produces biased variance and covariance estimates even when the missing-data mechanism is MAR or MCAR (Little and Rubin, 2020; Peugh and Enders, 2004). A modification of regression imputation is stochastic regression imputation, which aims to solve the issue of biased variance-covariance estimates by adding random residual terms to the imputed

values. Some types of parameter estimates are statistically consistent under MAR and MCAR using this method (Peugh and Enders, 2004). However, regardless of which form of regression imputation is used, the implementation becomes more complicated when missingness occurs on more than one variable and respondents differ on which variables are missing.

Weighting approaches

Weighting adjustments are missing-data methods that approach the phenomenon of missingness from a sample selection perspective, in which each member of the sample has some positive probability of being selected for the sample. It is supposed that the population of interest is composed of several subpopulations, and that one of these subpopulations is prone to nonresponse and is thus undersampled compared to the others. However, some participants with observed data may belong to the subpopulation that is prone to nonresponse. The rationale of weighting approaches is to differentially weight such participants to correct the bias that comes from undersampling the subpopulation that is prone to missingness. Such weighting approaches include propensity weighting (Czajka et al., 1992; Little, 1986; Rubin, 1985), and inverse probability weights (Kish, 1995; Potthoff et al., 1992; Stapleton, 2002). The values of observed variables may be used to help determine such sampling weights. However, the bias and sampling variance of mean estimates are sensitive to the particular choice of such variables: in some cases, the bias and sampling variance are only reduced when such variables are highly associated with both nonresponse and with the outcome variable (Little and Rubin, 2020, Table 3.1).

Likelihood-based methods

Likelihood-based missing-data methods fall under the umbrella of “model/distribution-based” methods and are also principled approaches. These missing-data methods are based on the likelihood from a model/distribution for the variables of interest (denoted here as Y), missingness indicator (denoted M), and, optionally, a set of fully-observed covariates (X). The “full likelihood” involves modeling of the missingness process and is given by

$$L_{full}(\theta, \psi | Y_{(0)}, X, M) = \int f(Y_{(0)}, Y_{(1)}, M | X, \theta, \psi) dY_{(1)} \propto f(Y_{(0)}, M | X, \theta, \psi) \quad (6)$$

where $f(\cdot)$ is the probability function of the involved variables, θ are the population parameters of interest, $Y_{(0)}$ are the set of observed values in the dataset, and ψ , X , and M are as previously defined. Starting from the joint density $f(Y, M | X, \theta, \psi)$ of the data Y and missingness indicator M , $Y_{(1)}$ can be integrated out to obtain $f(Y_{(0)}, M | X, \theta, \psi)$ used in the full likelihood of Eq. (6). Specifically, $\int f(Y_{(0)}, Y_{(1)}, M | X, \theta, \psi) dY_{(1)}$ can be simplified by factoring the joint distribution according to the selection model or pattern-mixture model factorizations described later in this article.

As the missingness process is typically unknown, it may be difficult to find its correct formulation. Thus, there is a risk that the full likelihood also may not be specified correctly even in cases when the data distribution is known. This is a threat to the validity of statistical inferences obtained from missing-data methods that are based on the full likelihood. In practice, the data distribution is often not known: this means there are two places in which the full likelihood may be incorrectly specified and thus two opportunities for reaching invalid statistical inferences.

In contrast, the “ignorable likelihood” does not involve modeling of the missingness process, which is given by

$$L_{ign}(\theta | Y_{(0)}, X) = \int f(Y_{(0)}, Y_{(1)}, X | \theta) dY_{(1)} \propto f(Y_{(0)} | X, \theta) \quad (7)$$

Thus, the ignorable likelihood is a simplified version of the full likelihood. Missing-data methods based on the ignorable likelihood may be used in cases when missingness is from the MCAR or MAR mechanisms. For this reason, the MCAR and MAR mechanisms are sometimes referred to as “ignorable” missingness. Missing-data methods that are based on the full likelihood should be used when missingness is from the MNAR mechanism. For this reason, the MNAR mechanism is sometimes referred to as “nonignorable” missingness.

Maximum likelihood

In general, maximum-likelihood yields estimates of population parameters that maximize the likelihood of the data. In the context of missing data and under the assumption of ignorable missingness, maximum-likelihood accomplishes this purpose via an algorithm and maximizes the ignorable likelihood given in Eq. (7). Maximum-likelihood can also be used when missingness is non-ignorable, in which case the method maximizes the full likelihood given in Eq. (6). Maximum-likelihood estimation under the assumption of ignorable missingness is sometimes referred to as full information maximum likelihood (FIML) or, in cases when the population distribution is assumed to be normal, normal-distribution-based maximum likelihood (NML). The term FIML is particularly common in the context of structural equation modeling (SEM).

When data contain missing values, maximum likelihood is most commonly implemented via the expectation maximization (EM) algorithm or variants thereof. Working with the full or ignorable likelihood, this algorithm alternates between an “E” step and an “M” step, in which the “E” step calculates various conditional expectations and the “M” step maximizes the expected likelihood of the complete data given the current estimates of those conditional expectations. Extensions or modifications of the EM algorithm are sometimes used in order to speed convergence of the algorithm or when the “M” step requires iteration. Such extensions of the EM algorithm include the ECM, ECME, AEEM, and PX-EM algorithms. Hybrid approaches such as gradient EM (Lange,

1995) or the accelerated EM algorithm (Jamshidian and Jennrich, 1993) may modify the EM algorithm by combining it with Newton-Raphson or Fisher scoring methods (Louis, 1982; Meilijson, 1989).

As a missing-data method, maximum-likelihood can provide estimates of the model parameters of interest directly when the analysis model (i.e., regression, SEM, growth curve model, etc.) is included in the formulation of the likelihood. Otherwise, maximum-likelihood can provide estimates of the mean and variance-covariance matrix of the population distribution that can be used for further statistical analyses. In such cases, the formulation of the likelihood involves the assumed population distribution (such as the normal distribution) and omits its relation to the analysis model.

The performance of the maximum-likelihood method has been extensively studied in the literature under a variety of circumstances and compared to other sophisticated missing-data methods. When the likelihood function is correctly specified, maximum-likelihood yields consistent and asymptotically normally distributed parameter estimates. The standard errors of maximum-likelihood estimates can be consistently estimated via the inverse of the corresponding observed information matrix. A disadvantage of the method is that maximum-likelihood does not supply predictions for the missing values themselves. This may be incompatible with certain statistical calculations such as residual diagnostics in regression.

Maximum-likelihood under the assumption of ignorable missingness is available as a missing-data method in several statistical software packages, such as SPSS, Mplus, SAS, and the “norm” package in R (Ported to R by Alvaro A. Novo. Original by J.L. Schafer, 2013).

Multiple imputation

Multiple imputation is a missing-data method that can be applied under both ignorable and nonignorable missingness, depending on the particular specifications involved. This missing-data method uses an algorithm to impute multiple plausible values for missing responses. Imputing several plausible values for a missing response is a strategy that reflects the inherent uncertainty associated with the missing response. The algorithm that is used in multiple imputation consists of four steps: (1) Impute missing values a total of D times according to the specified imputation model, yielding D complete datasets, (2) Conduct the statistical analyses of interest on each of the D complete datasets as if no missing values occurred, (3) Combine the set of D statistical estimates into a single set of “pooled” estimates, and (4) Obtain final inference(s) on the pooled estimates according to a set of pooling rules that are designed to correctly account for the variability associated with the pooled estimates.

The statistical assumptions that are made by multiple imputation come from the specified imputation model. The imputation model may assume ignorable missingness or allow for nonignorable missingness through modeling of the missingness mechanism. The imputation model also may make distributional assumptions: for example, continuous variables may be assumed to follow a normal distribution, nominal variables may be assumed to follow a multinomial distribution, and dichotomous variables may be assumed to follow an underlying latent normal distribution and modeled through logistic regression. The imputation procedure traditionally falls under the Bayesian framework, drawing from the predictive posterior distribution of missing responses. However, there are several other choices for creating imputations. A popular choice is predictive mean matching, in which missing values are replaced with observed responses from a pool of “donors”—subjects who are deemed to be similar to the subjects with missing responses on the completely observed variables. This method of creating imputations will always produce “permissible” values for the variable type; for example, missing responses on a discrete numeric variable will always be imputed with discrete values. Thus, predictive mean matching can be used for any variable type. However, this method has limitations: the quality of imputations is only as good as the pool of donors, which may suffer when the pool of donors is too small compared to the rate of missingness or when missingness is nonignorable. Imputations may also be created from random forest analysis or from CART, which are nonparametric methods borrowed from the statistical learning literature. Imputation models for nonignorable missingness include Heckman’s selection model (Galimard et al., 2016, 2018).

A popular multiple imputation approach is Chained-Equation Multiple Imputation, also called Multiple imputation via Chained Equations (MICE). This approach breaks from traditional MI methods in that it does not use the joint distribution of the variables to create imputations. Instead, missing values are imputed via a sequence of conditional distributions that describe how a given variable is related to the others in the dataset. Thus, this approach to multiple imputation requires the user to specify the number of imputations (D) as well as the number of iterations (t). The set of conditional distributions in Multiple imputation via Chained Equations may not necessarily correspond to a coherent joint distribution. Nevertheless, multiple imputation via chained equations can have good performance when the set of conditional distributions fit the data well, even though these may lack strict theoretical justification (Li et al., 2014; Little and Rubin, 2020). In such cases, it is recommended that the analyst checks that the imputed values are “reasonable” via diagnostic checks, perhaps checking that the distribution of imputed values is similar to that of observed values conditional on missingness propensities. There are several approaches to perform diagnostic checks, some of which are supported by statistical software (Abayomi et al., 2008; Bondarenko and Raghunathan, 2016; van Buuren and Groothuis-Oudshoorn, 2011). However, such checks can offer no guarantee regarding the true accuracy of the imputations—imputations may be far from their true values but still appear reasonable.

Special care must be taken when obtaining pooled estimates of certain statistical quantities. For example, standard errors will be underestimated if they are pooled by averaging across the D completed datasets due to the artificially increased sample size. Thus, pooling rules that correctly account for the variability of such statistical estimates have been developed. Such rules exist for standard errors, test statistics, and adjustments to the reference distribution for such test statistics and confidence intervals. In the context of regression, pooling rules have also been developed for R^2 and R^2_{adj} (Harel, 2009).

Choosing an appropriate number of imputations (and iterations, if using Multiple Imputation via Chained Equations) is an important issue for conducting multiple imputation. Standard recommendations have stated that as few as 5 or 10 imputations are sufficient to obtain reliable statistical estimates (Little and Rubin, 2020). However, statistical power and Monte Carlo error are important considerations in practical data analysis which may suggest that a greater number of imputations is optimal (Bodner, 2008; Graham et al., 2007; Horton and Lipsitz, 2001; Royston, 2004; Schafer, 1997; Von Hippel, 2009; White et al., 2011).

In such cases, the optimal number of imputations is related to the “fraction of missing information,” although this quantity may be difficult or impractical to calculate in some applications (White et al., 2011). One recommendation is to choose the number of imputations so that it is proportional to the actual rate of missingness. For example, if there is 40% missingness overall, then 40 imputations are sufficient (Bodner, 2008; Von Hippel, 2009).

Advancements in multiple imputation methods have been made for several data contexts, including for multilevel models (Enders et al., 2020; Grund et al., 2018). Multiple imputation is also available in many statistical software packages, such as SPSS, SAS, Mplus, and the mice package in R (van Buuren and Groothuis-Oudshoorn, 2011; RStudio Team, 2018). The miceadds package in R supplements the information provided by the mice package, such as pooled estimates of R^2 and R^2_{adj} according to the pooling rules in Harel (2009), Robitzsch and Grund (2021), van Buuren and Groothuis-Oudshoorn (2011).

Multiple imputation has several advantages. First, the imputation model can be specified very flexibly. This allows the missing-data method to be used for ignorable or nonignorable missingness. Under the assumption of ignorable missingness, the adoption of a nonparametric imputation model such as random forest analysis, CART, or predictive mean matching can sidestep issues arising from a misspecified imputation model. Second, multiple imputation provides a set of complete datasets which are easier to analyze. Disadvantages of multiple imputation are that proper pooling rules may still need to be developed for some multicomponent test statistics, a misspecified imputation model can lead to overestimated variances, and distribution violations of the imputation model can lead to estimated standard errors that are statistically inconsistent (Little and Rubin, 2020; Raghunathan and Rubin, 1998; Yuan et al., 2012). Furthermore, choosing an appropriate number of imputations may not always be straightforward, and a large number of imputations increases computational burden.

The performance of multiple imputation has been compared to that of maximum likelihood in many settings, including item response theory and analyses with mediation or moderation (Collins et al., 2001; Finch, 2008; McNeish, 2017; Schafer and Graham, 2002; Shin et al., 2017; Yuan et al., 2012; Zhang and Wang, 2013, 2017). However, the two methods are asymptotically equivalent under the assumption of normality and when Bayesian linear regression is used as the imputation model.

Models for nonignorable missingness

Models for nonignorable missingness are based on the full likelihood in Eq. (6) and operate by factoring the joint distribution of the data and missingness, denoted as $f(Y, M|X, \theta, \psi)$. Thus, such missing-data methods assume a distribution for the data and a distribution for missingness. A further assumption is that the statistical relationships in the missingness process itself are specified correctly—all relevant variables must be included together with any interaction or nonlinear terms that are involved in the true (but unknown) missingness process. Models for nonignorable missingness generally fall under one of two approaches, whose implementations differ across types of analysis model.

Selection models

Selection models aim to model the MNAR mechanism by factoring the joint distribution of Y and M as $f(Y|X, \theta)f(M|X, Y, \psi)$. That is, the joint distribution is factored into a distribution of the data given optional covariates and the distribution of missingness given the data and optional covariates.

A popular approach in the selection model framework for cross-sectional data is the Heckman selection model (Heckman, 1976). The Heckman selection model assumes the data are normally distributed and that $f(Y|X, \theta)$ can be modeled by regression, in which the outcome variable contains missing values. An equation for $f(M|X, Y, \theta)$ models the missingness process via regression, which is linked to the regression equation for $f(Y|X, \theta)$ through the error terms. Specifically, the residuals of these two regression equations are assumed to be correlated when missingness is nonignorable. Maximum likelihood estimation is typically used to obtain parameter estimates of the regression models. Heckman's selection model is sensitive to the assumption of normality, model misspecification, and requires that missingness is isolated to the outcome variable.

Selection models have also been developed for repeated measures. The approaches of Wu and Carroll (1988) and Diggle and Kenward (1994) assume that the analysis model is a latent growth curve model. The formulation of Wu and Carroll (1988) regresses the probability of missingness at a given time point on the intercepts and slopes of the individual growth trajectories through logistic regression equations. In this way, missingness is assumed to depend on all variables, including those after the timepoint missingness occurred. This model operates by making distributional assumptions regarding the latent intercepts and slopes for the growth trajectories. The formulation of Diggle and Kenward (1994) differs from that of Wu and Carroll (1988) in that the probability of missingness is regressed on the measured variables themselves. Missingness is allowed to depend on the current and previous measurement occasions and distributional assumptions are made regarding the repeated measures variables.

Software support for selection models under the assumption of normality and cross-sectional data are available in the “sampleSelection” R package and Mplus (Toomet and Henningsen, 2008). Software support for selection models with repeated measures are available in Mplus. This software uses the model suggested by Diggle and Kenward (1994).

Pattern-mixture models

As implied by its name, the method of pattern-mixture models assumes that each observed data pattern follows a specific model/distribution, and that the whole sample is a mixture of these patterns. This method factors the joint distribution $f(Y, M|X, \phi, \pi)$ as $f(Y|X, M, \phi)f(M|X, \pi)$, where π are parameters related to the probability of missingness patterns and ϕ are population parameters with components $\phi^{(k)}$ that correspond to the set of parameters associated with the k th missingness pattern. That is, the joint distribution is factored into: (1) a distribution of the data given optional covariates which is stratified by the missingness patterns observed, and (2) the distribution of missingness given optional covariates and probabilities of such missingness patterns. As a result of this stratification, parameters in ϕ associated with incompletely observed variables may not be identified for the corresponding groups of nonrespondents without specifying constraints.

Such an issue can be addressed by imposing certain restrictions on the values of ϕ . For example, for nonignorable missingness that depends on certain covariates (i.e., from the diffuse MNAR mechanism), a restriction may be that a subset of the parameters from the conditional distribution of the completely observed variables (say, y_1) given the incompletely observed variable (say, y_2) $\phi_{1.2}^{(k)}$ are the same across missingness patterns, i.e., $\phi_{1.2}^{(0)} = \phi_{1.2}^{(1)} = \phi_{1.2}$, where $\phi_{1.2}$ designates the set of parameters for the distribution of y_1 conditional on y_2 (Little and Wang, 1996). With a single variable containing nonignorable missing values, a common assumption is that the distributions of observed and missing responses differ by an intercept: that is, the mean of the distribution for nonrespondents is shifted from that of the distribution for respondents (as in Example 15.8 of Little and Rubin, 2020).

When two or more variables contain missing values, the number of restrictions on ϕ required for model identification depends on the number of completely observed variables p_1 relative to the number of variables with missing responses p_2 . Little and Wang (1996) discuss cases in which a pattern-mixture model may be just-identified, underidentified, or overidentified in the context of regression analysis. For overidentified pattern-mixture models, iterative methods are needed to obtain parameter estimates. However, the performance of the pattern-mixture-models suggested by Little and Wang (1996) suffers when there are more than two patterns of missingness (Little and Rubin, 2020; Tang et al., 2003).

In the context of repeated measures, pattern-mixture models may fit a growth model for each missingness pattern and place restrictions on the resulting growth parameter estimates. The approach of Hedeker and Gibbons (1997, 2006) uses a drop-out indicator as a predictor for the latent slopes and intercepts, and assumes equivalence of growth trajectories for two or more patterns of missingness—for example, between early and late drop-outs. The model also assumes that the covariance structure is the same across missingness patterns and that missingness arises from subjects who “drop out” of the study altogether. Other choices of constraints for the set of inestimable parameters in ϕ in the context of repeated measures are also possible (Enders, 2010, 2011; Demirtas and Schafer, 2003; Molenberghs et al., 1998; Thijs et al., 2002; Verbeke, 2000). Software support for pattern-mixture models is available in Mplus and SAS.

Bayesian methods

Bayesian methods for statistical inference can also be applied in the context of missing data for both ignorable and nonignorable forms of missingness. As with complete data, the method operates by drawing from the posterior distribution of the parameters of interest. Under ignorable missingness and with a chosen prior distribution $p(\theta)$ for the model parameters, the posterior distribution is $p(\theta|Y_0) \propto p(\theta) \times f(Y_0|\theta)$. In cases with a monotone missingness pattern and when a one-to-one function of θ can be found in which the corresponding parameters are *a priori* independent, the parameters of interest can be simulated from the posterior distribution directly based on the factored likelihood (Little and Rubin, 2020, Chapter 7). When these conditions do not hold, iterative methods should be used. Such iterative methods include data augmentation or Gibbs' sampler.

Data augmentation is an iterative Bayesian method that alternates between an “I” step and a “P” step to eventually produce a draw of the joint posterior distribution of missing values and the parameters of interest given the observed data (Tanner and Wong, 1987). Specifically, for the t^{th} iteration, the “I” step imputes missing values $Y_1^{(t)}$ based on a draw from the conditional density $p(Y_1|Y_0, \theta^{(t-1)})$, and the “P” step draws values of $\theta^{(t)}$ from the conditional density $p(\theta|Y_0, Y_1^{(t)})$. Once the algorithm has proceeded long enough to converge to a draw from the target joint posterior distribution, the values of θ and Y_1 are kept from the final iteration T . This process is repeated independently a total of D times to obtain D draws from the posterior distribution of θ and the posterior predictive distribution of Y_1 . Inference about θ is based on the D draws from its posterior distribution $p(\theta|Y_0)$ which may be summarized by the posterior mean and variance-covariance.

In cases when it is difficult to obtain draws from the joint posterior distribution directly—such as scenarios in which θ is multivariate and its components are not independent—Gibbs' sampler can be used. For the t^{th} iteration, the “P” step of data augmentation now involves a series of conditional distributions, in which the values of a parameter $\theta_j^{(t)}$ are drawn from conditional distributions given the current draws of other parameters $\theta_{j-1}^{(t)}, \theta_{j-2}^{(t)}, \dots$. Like data augmentation, the algorithm eventually converges to a draw from the target joint posterior distribution and should be independently run a total of D times to obtain D draws from the target distribution $p(\theta|Y_0)$.

Both data augmentation and Gibbs' sampler may not work well if the number of iterations is too small. However, several methods have been developed to assess or improve the convergence of the sequence of draws (Gelman et al., 2013; Gelman and Rubin, 1992; Geyer, 1992; Liu and Rubin, 1996, 2002). The usual limitations of Bayesian methodology are also applicable to their use as missing-data methods—such as when $f(Y_0|\theta)$ is misspecified as normal for convenience (see e.g., Yuan and Gomer,

2021) or the potential for a prior to overwhelm the information provided from the data, particularly with small sample sizes (Gelman, 2006; McNeish, 2016; Smid and Winter, 2020; Smid et al., 2020). Software support for Bayesian missing-data methods includes Mplus, SAS, and the “brms” R package (Bürkner, 2017).

Statistical learning methods

CART

A relatively new missing-data method adapted from the statistical learning framework is Classification and Regression Trees (CART) (Breiman et al., 1984). This nonparametric approach relies on inverse probability weights to operate (McArdle, 2013). The implementation of CART typically assumes missing values are MCAR, although a few authors claim that the particular relationship between missingness and the outcome variable has a greater impact on CART’s performance than the missing-data mechanism (Ding and Simonoff, 2006; Saar-Tsechansky and Provost, 2007).

As a missing-data method, CART aims to find the best cut-off point on values of a variable that will separate or “split” the group of respondents from the group of nonrespondents. However, this process may need to be repeated several times in order to achieve good separation of the groups. This yields a tree-like structure in which each “node” corresponds to a different variable or different cut-point on a variable that was considered in a previous step. The end result classifies subjects into several subgroups; each subgroup is composed entirely of respondents or nonrespondents (to the fullest extent possible). The predicted probabilities associated with being classified into the subgroups are inverted and then used as sampling weights. CART may be used to create a single artificially complete dataset or paired with multiple imputation, although the results obtained from a single dataset may be problematic (van Buuren, 2018).

A potential drawback of CART is that it is prone to overfitting—in other words, it produces a tree structure that optimizes separation in the current dataset at the cost of generalizing well to others (Crawford, 1989). This shortcoming can be addressed by preventing the tree from “growing” too large through the use of stopping criteria, in which the final subgroups are required to have a minimum sample size. A different strategy is to “prune” a large tree structure via cost-complexity pruning, in which the misclassification rate of respondents vs. nonrespondents is balanced against tree complexity. At the time of this writing, there is still no consensus regarding which of the two strategies is best, although it is a subject of ongoing debate (Berk, 2009; Hayes et al., 2015; Louppe, 2014).

Random forest analysis

Random forest analysis is another statistical learning approach that has been adapted for use as a missing-data method (Breiman, 2001). Random forest analysis operates in a similar way to CART and under the same assumptions of missingness. However, while CART creates a single tree structure, random forest analysis is an ensemble method that creates a “forest” of many such regressions trees and each is based on a bootstrapped sample of the data. Missing values can be imputed based on the values of complete cases and the resulting sampling weights to yield a single complete dataset (Breiman, 2003). However, both random forest analysis and CART can be used as an imputation model in multiple imputation and are supported in the “mice” R package (van Buuren and Groothuis-Oudshoorn, 2011).

Other methods

Several other statistical learning approaches have also been adapted for use as missing-data methods. These include classification methods such as k-Nearest-Neighbors (kNN) (Batista and Monard, 2001; Huang and Lee, 2004; Wasito and Mirkin, 2006; Zhang, 2011, 2012), k-means or clustering methods (Fujikawa and Ho, 2002; Li et al., 2004; Patil et al., 2010; Zhang et al., 2008), artificial neural networks (Nelwamondo et al., 2007; Setiawan et al., 2008), and support vector machines (SVM) (Mallinson and Gamerman, 2003; Sivapriya et al., 2012; Suykens et al., 2002). These missing-data methods are often used as single-imputation strategies, although it is possible to use them in a multiple imputation context (Sivapriya et al., 2012). Note that even these advanced methods will lead to underestimation of variances and covariances if they are used as single-imputation strategies, and that articles often evaluate the performance of these methods in terms of prediction accuracy of the missing values themselves rather than on the quality of parameter estimates.

Threats to proper handling of missing values and possible remedies

Violated distribution conditions

Note that likelihood-based missing-data methods such as ML and MI only produce valid statistical inferences when the likelihood function is correctly specified. When these inferences are based on the ignorable likelihood of Eq. (7), the missingness mechanism must be MAR or MCAR and the distribution of the data must match the distribution assumed by the likelihood. It is a well-known fact that real data are seldom normally distributed, as has been repeatedly pointed out in meta analyses (Blanca et al., 2013; Cain et al., 2017; Micceri, 1989). Nevertheless, most researchers assume normality when implementing ML and MI (NML, NMI) in data analysis due to a lack of alternative distributions with multivariate data. Practical distribution violations cause NML to become “pseudo ML,” and NMI to become “pseudo MI.” FIML (full information maximum likelihood) is just a nickname for a widely used methodology unless the population distribution is truly multivariate normal. With skewed and kurtotic data, the NML

missing-data method can still yield consistent parameter estimates when the population distribution satisfies certain conditions (Yuan and Bentler, 2010). Consistent standard errors of the NML estimates can also be obtained via sandwich-type covariance matrices (Yuan, 2009b). However, such conditions are hard to verify in practice. It is likely that NMI also yields consistent parameter estimates under the same conditions specified in Yuan and Bentler (2010); see Yuan et al. (2012) for a discussion of the rationale. However, NMI cannot generate consistent standard errors for the NMI estimates because nonnormally distributed data are replaced with normally distributed ones (Yuan et al., 2012).

Tests of normality

Methods exist to test multivariate normality with complete data (e.g., Liang and Ng, 2009). However, with incomplete data, and especially under the MAR and MNAR mechanisms, the distribution of the observed data can be skewed and kurtotic even when the underlying population distribution is multivariate normal (Jamshidian and Yuan, 2014). This makes it hard to justify the NML and NMI methods in operation, because they depend on conditions that are not verifiable. Nevertheless, it is still desirable to acknowledge possible distribution violations in practice for these methods to be of a scientific nature. In this direction, the measure of multivariate kurtosis (Mardia, 1970) has been extended to incomplete data (Yuan et al., 2004) which is also available in statistical software (Bentler, 2006).

Robust methods

There are developments pertaining to NML methods that yield consistent standard errors and rescaled test statistics for mean and covariance structural models with incomplete data (Yuan, 2009b; Yuan and Bentler, 2000). With real data whose distributions possess heavier tails, robust methods have been shown to yield much more reliable results in statistical modeling (Wilcox, 2017; Yuan and Gomer, 2021). Robust methods via the *t*-distribution-based maximum likelihood (TML) have been developed by Little (1988a). Yuan et al. (2016) developed more general robust methods via estimating equations, which not only yield robust estimates but also provide an approach to obtain consistent standard errors for the robust parameter estimates as well as more reliable test statistics in mean and covariance structure analysis (Tong et al., 2014).

Comparing distribution violations against non-ignorable missingness, results show that data from a heavier-tailed distribution can cause much more damage to the NML missing-data method than MNAR missingness does (Yuan and Savalei, 2014), especially when data are contaminated. Monte Carlo results also show that robust methods yield close to optimal results even when the population distribution is normally distributed (Yuan et al., 2015).

The use of auxiliary variables

Datasets in the social sciences often contain a large number of variables. Some of these variables may not be of particular research interest and are thus excluded from statistical analysis. However, as has been presented earlier, the MAR mechanism is defined via conditional distributions; and omitting such observed variables from missing data procedures is equivalent to failing to observe these variables in the first place. This presents a scenario for the introduction of auxiliary variables: variables that are related to missingness but are not involved in substantive analysis. Proper use of auxiliary variables can lead to improved analysis and more reliable results, and it is best carried out using a two-stage procedure. In the first stage, auxiliary variables are included in the estimation of saturated models (means and variances-covariances). The second-stage analysis is conducted using the estimated means and variances-covariances corresponding to the substantive variables from the first stage. This two-stage procedure is easy to implement both under NML and under robust methods (Savalei and Bentler, 2009; Yuan and Lu, 2008; Yuan and Zhang, 2012). Software support for this procedure is also available in the context of structural equation modeling in the R package “rsem” (Yuan and Zhang, 2020).

There exist recommendations to include a large number of auxiliary variables, or, in other words, “the more the better” (e.g., the inclusive strategy in Collins et al., 2001). However, these recommendations are based on Monte Carlo studies with normally distributed populations. In practice, including auxiliary variables whose distributions contain heavier tails can make the resulting NML estimates less accurate, even though the missing data mechanism becomes MAR (Yuan and Savalei, 2014). There are methods for selecting auxiliary variables based on their effects on the existing estimates (Yuan, 2009a). However, regardless of how auxiliary variables are chosen, there is no existing procedure that allows one to conclude that the resulting mechanism actually becomes MAR. This is because the MNAR mechanism is on a continuum that is characterized by the extent to which missingness is influenced by the missing values themselves. Including auxiliary variables may nevertheless bring the resulting estimates closer to the population values, but it is hard to claim that the missingness in any given analysis of incomplete data is ignorable.

Missing-data mechanism uncertainty

In practice, the underlying missing-data mechanism is often unknown. This can be problematic if the chosen missing-data method assumes ignorable missingness while the true missingness process is actually nonignorable. Missing-data methods designed for nonignorable missingness do so by making untestable assumptions, so their performance may also be uncertain in practice. For this reason, it is better not to use these methods when missingness is ignorable. An incorrect diagnosis of the missing-data mechanism has consequences for the validity of statistical inferences (Collins et al., 2001; Gomer and Yuan, 2021; Little and Rubin, 2020; Smuk et al., 2017). Thus, uncertainty regarding the true missing-data mechanism is an important issue in missing data analysis.

Tests of the missingness mechanism

One way to approach the issue of missing-data mechanism uncertainty is through statistical methods that seek to identify or test the missing-data mechanism directly. Although this is an appealing idea, such methods fall short of achieving this goal. A further complication is that such tests of the missingness mechanism are often misused in practice.

Tests of MCAR

Tests of the MCAR mechanism operate by testing the homogeneity of means and variances-covariances across missingness patterns. Under MCAR, the estimated means and variances-covariances from each of these patterns are unbiased for the overall population mean and variance-covariances, so equality of means and variance-covariances across missingness patterns is a necessary condition for the MCAR mechanism (Rhoads, 2012; Yuan et al., 2018). Thus, rejecting the null hypothesis suggests that the true missing-data mechanism is not MCAR. Perhaps the most famous test of the MCAR mechanism is Little's test of MCAR (Little, 1988b), which tests equality of means and variances-covariances through a likelihood ratio test statistic. A modification of this test using generalized least squares was developed by Kim and Bentler (2002). Other developments for tests of the MCAR mechanism have been made for scenarios with small samples sizes within missingness patterns (Jamshidian and Jalal, 2010), categorical data (Park and Davis, 1993), repeated measures (Park et al., 1993), and generalized estimating equations (Chen and Little, 1999; Qu and Song, 2002).

Unfortunately, homogeneity of means and variances-covariances is not a sufficient condition for MCAR (Rhoads, 2012); and indeed, there are many conditions in which homogeneity of means and variances-covariances hold even under the MAR and MNAR mechanisms and under multivariate normality (Yuan et al., 2018). For this reason, tests of MCAR can only provide credible evidence against the MCAR mechanism, rather than in favor. Nevertheless, misuse of these tests is common.

Tests of MAR

Tests of the MAR mechanism may test the MAR assumption against a specific MNAR alternative. Such tests may take the form of a model-based likelihood ratio test (Zhou et al., 1999), which assume that the full likelihood for nonignorable missingness has been correctly specified; or, equivalently, that the model of the missingness process is correct (Rhoads, 2012). Unfortunately, it has been shown that for every MNAR model, an MAR model can be found that has equivalent fit to the data (Molenberghs et al., 2008). This means that such likelihood ratio tests can only provide evidence against the MAR mechanism in cases when there is strong *a priori* belief in the MNAR model (Molenberghs et al., 2008).

Several methods claim to test the MAR mechanism or ignorable missingness against a more general alternative. However, such tests actually evaluate a weaker condition, such as that data are Observed At Random (OAR), $P(Y_{(0)}|R) = P(Y_{(0)})$ (Rubin, 1976), which may not even be a necessary condition for ignorable missingness in some analysis model contexts (Rhoads, 2012). Tests of the MAR mechanism that actually evaluate OAR include those of Katz (2006) and Sherman (2000). Tests may instead evaluate OAR conditional on a fully observed vector of covariates (Park and Davis, 1993) or OAR conditional on baseline responses in the context of repeated measures (Donaldson and Moinpour, 2005). Thus, the stated goal of such tests differs from what is actually evaluated. This problem is likely to exist for any test of the MAR mechanism that claims to evaluate MAR against a general alternative (Rhoads, 2012).

Sensitivity analysis

Sensitivity analysis is a statistical approach to assess the sensitivity of results to the missing-data mechanism or to the departure from the MAR assumption (Little and Rubin, 2020). Typically, sensitivity analysis involves explicit modeling of the missingness process, in which the user specifies a series of values for a "sensitivity parameter" that controls the degree of departure from the MAR mechanism. By examining the fluctuations in final statistical inferences across distinct values of the sensitivity parameter, researchers can assess the stability of their statistical inferences with respect to missing-data mechanism uncertainty. Sensitivity analysis is a widely studied topic, although many developments have come from biostatistics or related fields.

In general, sensitivity analysis consists of three steps: (1) choosing a range of values for the sensitivity parameter; (2) carrying out statistical analyses for each of the chosen values; and (3) incorporating the results to obtain final statistical inferences. With respect to the last step, there are three popular approaches used for decision-making regarding such final statistical inferences (The Prevention and Treatment of Missing Data in Clinical Trials, 2010). One approach is to report the upper and lower bounds of parameter estimates obtained across a plausible range of values for the sensitivity parameter or the upper and lower bounds of such estimates (Leacy et al., 2017; Molenberghs and Kenward, 2007). Another approach is to conduct statistical analyses under the assumption of MAR and determine which values of the sensitivity parameter would overturn the current set of statistical conclusions (Campbell et al., 2011; Liublinka and Rubin, 2012; Yan et al., 2009). The third approach is to obtain a summarized version of statistical inference by averaging over values of the sensitivity parameter according to a set of principles (Carpenter et al., 2007; Siddique et al., 2012).

Several methods for conducting sensitivity analysis are multiple-imputation-based approaches. One of the most popular methods is "multiple imputation with delta adjustment," which adds a fixed offset to the linear predictor of the imputation model to shift the mean of the distribution of nonrespondents compared to that of respondents (Carpenter and Kenward, 2008; Carpenter et al., 2013; Leacy et al., 2017; Rubin, 1977; van Buuren et al., 1999). An alternative is to switch the order of operations such that the

fixed offset is added to the imputations themselves instead of the linear predictor (Giusti and Little, 2011; Little and Rubin, 2020; van Buuren et al., 1999). Many other multiple-imputation-based approaches exist (Carpenter et al., 2007; Hsu et al., 2020).

Reference-based approaches to sensitivity analysis are sometimes used in the context of clinical trials, in which statistical analyses are conducted under various assumptions regarding missing values or protocol deviations. One such assumption might be that the mean drug effectiveness for drop-outs from the treatment group is equal to the observed mean of the placebo group at unobserved time points. Another assumption might be that drug effectiveness for drop-outs at unobserved time points is equal to the marginal mean at the last observed time-point. Several other assumptions may also be considered (Ayele et al., 2014; Carpenter et al., 2013; Cro et al., 2016; Smuk et al., 2017).

Tipping-point analysis is an approach to sensitivity analysis that finds the values of missing responses required to overturn the current statistical conclusion (Yan et al., 2009). The plausibility of these values can then be evaluated by the researcher or agency tasked with reviewing the findings. Statistical results obtained under this strategy have an intuitive interpretation. Graphic displays have also been developed to visualize such tipping-point analyses (Campbell et al., 2011; Liublinska and Rubin, 2012).

Conclusion and recommendations

There are many statistical procedures available to the data analyst when handling missing values. In our opinion, the best practice is to use substantive judgment to diagnose the missing-data mechanism and use a likelihood-based missing-data method that is appropriate for such a missingness mechanism or a robust method when the distribution of the observed variables contains heavy tails. The particular circumstances of the data (such as the modeling context) may naturally suggest one missing-data method over another. If there is uncertainty regarding the underlying missing-data mechanism, we recommend conducting sensitivity analysis to determine the extent to which statistical conclusions are influenced by the assumption of missingness mechanism. Tipping-point analysis or approaches that provide a single summarized version of statistical inferences may be the most straightforward to interpret, and thus may be a suitable choice for work that will be published in a journal where such analyses are uncommon.

We caution against the use of single imputation missing-data methods in practice. Note that several sophisticated missing-data methods borrowed from the statistical learning literature fall under this category, unless they are instead used as the imputation model in multiple imputation. We also caution against tests of the missingness mechanism, but such tests can be conducted responsibly if their results are interpreted carefully in the context of their limitations. In practice, it might be the case that the underlying population distribution is unknown and all three types of missing-data mechanisms (MCAR, MAR, MNAR) co-exist within the same pattern of missingness. In such cases, methods based on multivariate normality or that assume a specific missing-data mechanism may not perform well (Gomer, 2019). Caution should be used in the application of existing missing-data methods whenever such conditions are suspected.

Graphs are the intermediary between information and understanding.

with our apologies to Hans Hofmann (Friedel and Dickey, 1998).

Successfully negotiating the modern world often requires full and facile comprehension of quantitative phenomena. Experience gathered over more than three centuries has taught us this is best done by transforming the evidence into various kinds of pictures, so that we can enlist the remarkable power of the human visual system to rapidly decode and store complex information. Tracing the evolution of data visualization reveals many mysteries whose solution requires that we begin at the beginning.

Evolution of recording numbers

The idea of a number is very old indeed, and ancient ways of writing down numbers can be traced back to Paleolithic tally sticks (dating from the Aurignacian, approximately 30,000 years ago), which had notches cut into a bone, ostensibly to represent counts of something of interest. For example, such counting sticks were subsequently used to keep track of domestic animals. A notch was made when an animal was released to pasture and then later, when they returned, the shepherd's thumb would move down the stick, notch by notch. If no notches remained after the last animal returned, the shepherd would be assured that all was well. Such a system, though vastly better than relying on memory, had room for improvement. Adding an animal was easy, just another notch, but subtracting (perhaps because of a predator in the neighborhood or mutton for lunch) was more difficult and might require carving a new stick. Keeping separate track of several kinds of animals (e.g., goats and sheep or males and females) could be done with separate sticks for each type, but it would quickly become cumbersome to carry them around and to remember which was which.

Over time, the system of counting sticks evolved. The pre-Columbian Incans transformed their counting sticks into Quipus, ropes into which they tied knots that served the same role as notches. But knots could be untied, allowing subtraction. Also, two or more such ropes, each representing a different kind of animal, could be tied together and easily wrapped around the waist or thrown over the shoulder. Over time the Quipu evolved to include a summary: knots on the bottom portion of the rope each represented a single animal, but when ten knots accumulated, they were untied and a single knot representing ten was tied higher up on the rope. Some Quipus had three levels of knots, with a knot on the topmost level representing one hundred. These typically were above the joining of several strands (say goats, sheep and pigs), to indicate a grand total. In the evening, Quipus were sometimes hung on the wall of its owner's dwelling as a display of the family's wealth. We assume that the use of a base-ten for the construction of Quipus was strongly related to having ten fingers, which almost surely was the basis for all subsequent counting devices. Had the Incans had six fingers on each hand, there is little doubt that their mathematics would have been base twelve (Fig. 1).

The same forces that propelled the evolution of counting to yield the Quipu were at work in the Roman counting system, where a single knot became the written symbol "I" and a count of three was simply "III". But instead of untying the knots and replacing them with another knot in a different place, Romans substituted a new symbol "V" to mean five and still another symbol (X) for ten, and so on. The position of the symbol had little meaning except when indicating subtraction (e.g., IV) to avoid possibly confusing repetition (IIII). The Roman system was an obvious formalism of the humble tally (/, //, ///) still in use today.

Roman numerals were systematic, but their use for anything beyond record keeping and decoration was cumbersome. Try to imagine how Roman engineers could have built anything whose construction required computation of a precise measurement (e.g., how would you multiply 6342 by 18,327 with Roman numerals?). Despite this grave limitation, the evolution of written numbers, at least in Europe, was in stasis until the great Italian mathematician Leonardo Fibonacci (c.1175–c.1250) visited the Middle East during the time of the third Crusade.

In his travels in North Africa Fibonacci met with Middle-Eastern merchants and learned about the Hindu-Arabic numeral system, whose key component was zero. Upon his return Fibonacci told an engineer friend about this marvelous system, which used the digits 0–9 and place value to represent numbers but met with no enthusiasm. His friend rebuffed him, explaining that although this new method of recording numbers sounded interesting, he had a pressing problem in long division that had to be completed by next November and so he had no time to spare. This experience motivated Fibonacci to publish his justly famous 1202 treatise *Liber Abaci*. His book laid out in detail how the new system could be used in bookkeeping; interest calculations, money changing and other practical matters, and soon Roman numerals were relegated to being primarily decorative.

Using numbers

The search for truth has been a theme throughout human history. This search comprises two hierarchical categories—Do we use evidence? And, if so, what sorts of evidence have validity for the situation at hand?

The exploration of these great questions is called epistemology.

Epistemology is almost a foreign word and concept in common discourses. It typically makes its initial appearance, adjoined to metaphysics and phenomenology, as part of a trinity in the requisite undergraduate introductory philosophy course. But it rarely makes an impact on everyday life. Its definition usually contains a phrase like a “method for gaining knowledge,” which might translate into “Scientific method” which might then be specialized to “procedures used by actual practicing scientists.”

The iconic American physicist Richard Feynman provided, as only he could, a clear description of modern epistemology. In his famous Messenger Lectures, given at Cornell in 1964 (subsequently anthologized in his 1965 book *The Character of Physical Law*) he said,

In general, we look for a new law by the following process. First, we guess it. Then we compute the consequences of the guess to see what would be implied if this law that we guessed is right. Then we compare the result of the computation to nature, with experiment or experience, compare it directly with observation, to see if it works. If it disagrees with experiment it is wrong. In that simple statement is the key to science.

It does not make any difference how beautiful your guess is. It does not make any difference how smart you are, who made the guess, or what his name is—if it disagrees with experiment it is wrong. That is all there is to it.

Feynman answered the epistemological question of how and when evidence should be used by placing it in an exalted position. Evidence vetoed all else. Yet strangely, at least to us, this point of view has never been universal.

We hear the term “evidence-based decision making” in many fields: medicine, education, economics and political policy, to pick four. The implication is commonly that this is a new and modern way to try to solve contemporary problems. If what we are doing now is evidence-based, what were we doing previously?¹

How can we consider the use of evidence in science new? Hasn’t evidence been at the very core of science for millennia? The short answer is no. Making decisions evidence-based has always been a tough row to hoe, for once you commit to it, no idea, no matter

Fig. 1 A descriptive Quipu. Urton, Gary, 1998. From knots to narratives: reconstructing the art of historical record keeping in the Andes from Spanish transcriptions of Inka Khipus. *Ethnohistory* 45(5): 409–438, doi:10.2307/483319. JSTOR 483319.

¹Googling the term “Evidence-Based Medicine” reveals that the earliest reference is 1992. When I suggested that prior to that time medicine must’ve been faith-based my boss, a physician, said that he thought that it was intelligently designed.

how beautiful, no matter how desirable, can withstand an established contrary fact, regardless of how ugly that fact might be. The conflict between evidence and faith in the modern world is all around us, even in scientific issues for which faith is not required. So it is not surprising that using evidence to make decisions is taking a long time to catch on. The formal idea of using evidence as a method for gaining knowledge is often dated, as are so many things, with Aristotle (384 BC–322 BC). Aristotle diverged from his teacher Plato's purely rational approach by advocating the crucial inclusion of experience.² Aristotle famously studied the prenatal development of chickens by collecting a number of freshly laid eggs and then sequentially opening them, one each day, and noting the changes in the development of the chick embryos that he observed within them.

But the path from Aristotle to Feynman was not smooth. Once one commits to using evidence to make decisions, facts take precedence over opinion. And not all supporters of an empirical approach had the muscular support of Alexander the Great. Hence it took almost 1500 years before it briefly reappeared with Roger Bacon [1214–1292], who observed that,

Reasoning draws a conclusion, but does not make the conclusion certain, unless the mind discovers it by the path of experience.

But once again it slipped away, only to gain a firmer foothold with the work of Francis Bacon [1561–1626] who re-popularized the formal use of evidence, which was subsequently expanded and amplified by the British empiricists John Locke [1632–1704], George Berkeley [1685–1753], and especially the influential Scot David Hume [1711–1776], whose 1738 *Treatise on Human Nature*, as well as his 1741 *Essays, Moral and Political*, had a profound influence on Adam Smith, Jeremy Bentham and Immanuel Kant.

Although it took a very long time, by the late 18th century the stage was set. There was the beginning of a reasonably broad agreement on what constituted evidence, coupled with the by now well-established Hindu-Arabic number system, which itself provided a workable format for describing quantitative phenomena. And there were important and vexing problems requiring solutions, as well as a growing impetus to gather informative data. But what was lacking was a way to look at numbers and see meanings.

It is natural to ask how best to extract meaning from numbers. The answer is to transform numbers, which must be read, into pictures that could be seen. In doing so we enlist the extraordinarily powerful visual system, which allows us to see structure and, most importantly, to find what we were not expecting. This unanticipated benefit, obtained by visualizing quantitative evidence, profoundly changed the way science operated. It made the theoretical plotting of points with the goal of finding suggestive patterns possible and, because of an evolving string of successes, acceptable. Those wildly successful applications helped the evolution of what has become one of the most powerful tools for scientific discovery and for the communication of phenomena to those who could not be present when they occurred.

The story of the origin and development of the various kinds of data visualization forms the basis of this article. Although the notion of looking at quantitative measures of observations (numbers) to uncover meaning is surprisingly modern, the idea of visualizations is ancient.

There are two types of graphics that in a sense are antithetical to one another, yet both are critically useful tools.

The marvelous discovery of graphical methods to visualize data is usually dated to 1786, specifically the publication of William Playfair's *Atlas*, though there were earlier stirrings of the idea. Playfair's work, however, represented a dramatic development: spatial representation of data—e.g., time, value of imports, and value of exports—that were not, in their essence, spatial. There was no *a priori* logical basis for believing that such a representation would bear fruit, but it did. In 1822, Playfair happily reported that in 1787 France's King Louis XVI, after reading his *Atlas*, said, "they (the graphs) spoke all languages and were very clear and easily understood." Plotting of points in the search for unexpected patterns is now in full force. Mining big data intelligently would be insuperably more difficult without data graphics.

The sorts of graphics just described are defined by what is usually a synthetic spatial representation of data that are not, in their essence, spatial. They extend the visual idea of a two-dimensional map or town plan to data maps. There is a very long list of contemporary accounts explaining, exploring, and expanding the range of graphic possibilities. A modern list must include Bertin (1973) keystone explication, Tukey (1977) classic that called for a radically new graphical approach to statistics (the birth of "data science"), and Tufte (1983) masterful exposition showing that effective displays could provide "beautiful evidence." There has been a torrent of valuable additions since.³ Such applications, in which the word "graphic" is a noun, we will refer to as Type I graphics.

But there is a second definition of the word graphic, when it is used as an adjective with the meaning of *literal lifelikeness*—as in "graphic violence" or "graphic novel." This definition is quite the opposite of the synthetic displays that now dominate modern science. Ironically, this second definition is far older than the one that Merriam-Webster lists first, as are many of the data displays that represent it. These graphics not only satisfy the first goal of visualization, which is to answer basic questions, such as how do I get there, how do I do it, what happened, or even the causal, why did it happen? But they also serve the deeper purpose of acting as an intermediary between information and understanding.

²Aristotle was certainly not the first to advocate the critical advantages provided by empirical evidence. Sun Tzu [544–496 BC] predated Aristotle by two centuries and was the author of the widely cited *The Art of War*. In it he was very clear about the value of direct experiential knowledge. He wrote that, "Foreknowledge cannot be gotten from ghosts and spirits, cannot be had by analogy, cannot be found out by calculation. It must be obtained from people; people who know the conditions of the enemy."

³To learn more, the interested reader could do no better than the rest of Edward Tufte's trio of graphical wonders (1990 and 1996) and, being unafflicted with modesty, we also recommend some of our earlier descriptions; more specifically Wainer (1984, 1993, 1997, 2000, 2005, 2009, 2012, 2014) and, most recent, Friendly and Wainer (2021).

To illustrate the power of these “graphics of the second kind” and the questions they answer, we have chosen to look at two especially compelling examples drawn from the 18th and 19th century, specifically at examples of shipbuilding and the physical character of a woolly mammoth; of course, there are many more. The common characteristic of these graphics is that they provided a uniquely effective way to think about, reason about, and understand scientific phenomena; they illustrate how powerful and how broadly useful visualizations can be in the service of scientific and practical explanation.

How to build a ship from a forest

Looking at history from a modern perspective often reveals mysteries. One such mystery emerges when trying to imagine the combination of science and craft required for shipwrights to efficiently transform the contents of a local forest into a 19th century, 24-gun frigate for the British Royal navy. This task must have involved a shipwright looking carefully at each tree to see what parts could be used for different purposes and somehow communicating those arboreal insights to a sawyer for execution.

Fig. 2 from [Panckoucke \(1783\)](#) *marine Encyclopedia*, shows that communication was graphical. Shipwrights drew a picture of a portion of the forest and on each tree were inscribed the parts of the ship they needed that were to be the contribution of that tree. Long straight tree trunks would become the ship’s masts; shorter straight sections would be its spars or yardarms, and forked sections would naturally fill and buttress the bow or various overhangs. This graphic is an early example of visual thinking and visual explanation that compactly answers the questions: How do I do it? How do I transform the trees like those found in a local forest into the necessary parts to build a ship? Such instructions could be expressed verbally, similar to asking for turn-by-turn directions when you are lost. But, as with asking for directions and being drawn a map, this graphic gives immediate and memorable instructions that can be used and the lessons implicit in it are easily generalized for future use.⁴

What does a woolly mammoth look like?

In 1801, Charles Willson Peale, a curator of one of the first museums of natural history in the US, put a mammoth skeleton on display in Philadelphia’s Philosophical Hall. The skeleton was a mixture of anatomy and guesswork, with missing bones replaced by wood or papier-mâché. The exhibit proved so successful that Peale took it on the road, displaying it in both London and Bristol. A contemporaneous drawing based on Peale’s skeleton, ([Fig. 3](#)), however, shows that, his display had numerous anatomical mistakes—he even had the tusks upside down.⁵

Fig. 2 Plate 103 in [Panckoucke \(1783\)](#) “*Encyclopédie Méthodique Marine*” showing how to harvest specific ship parts from trees (Our thanks to Kaicong Wu, who brought this example to our attention) http://www.epaves.corsaires.culture.fr/mediatheque/communs/images/grand_formats/1/449_4.jpg.

⁴Panckoucke was, famously, the publisher of the *Encyclopédie méthodique*, the successor to the *Encyclopédie* of Diderot & d’Alembert whose 1751 publication marked the editors valiant attempt to represent the thought of the Enlightenment and to “change the way that people think.”

⁵Peale’s construction was based on available fossilized bones, contemporary anatomical knowledge, analogical reasoning based on his knowledge of elephants. But there had to be other, even less accurate, sources based on his confusion about the mammoth’s character—for example he described it as carnivorous.

But modern reconstructions have it right—upward curling tusks, humped shoulders, downward sloping spine. We should note that our modern conception was not solely obtained by studying bones but by looking closely at the art of those who observed the animals first-hand. More than half of the hundreds of drawings left by Paleolithic artists on the walls of the Rouffignac Cave in the south of France were of woolly mammoths. The drawings answer the question: what did the animal look like? See Fig. 4. What led Peale astray was that he didn't have the benefit of the visualizations of Paleolithic artists to guide him. Having an accurate answer to "what did they look like?" means that investigators can at least begin on the right path. The value of such visual communications has often proved to be profound. Through such depictions, the original artists, their very bones long dust, have reached out across the centuries and aided modern understanding.

A practical type I graphic—Marey (1878) train schedule without showing locomotives

The popularity of visualizations owes much to the almost religious fervor of scientists and epistemologists of the 19th century who sought to banish subjectivity from science. They "drew on a number of techniques including inferential statistics, double-blind clinical trials, and self-registering instruments to hold subjectivity at bay".⁶ But, the oldest and most important, of these was visualization.

By 1878 the French physiologist Etienne Marey, whose graphic schedule of all the trains between Paris and Lyons (reproduced in Fig. 5) provides a powerful illustration of the breadth of value of this approach, expressed the feelings of most natural scientists of the value of graphical representation,

There is no doubt that graphical expression will soon replace all others whenever one has at hand a movement or change of state—in a word, any phenomenon. Born before science, language is often inappropriate to express exact measures or definite relations.⁷

Marey (1878, p. iii).

Fig. 3 An 1802 drawing of the mammoth, based on Peale's skeletal reconstruction which they characterized as a "carnivorous animal of immense size" <https://goo.gl/images/8xCpmd>- our thanks to Stephen Stigler for this figure.

⁶From p. 17 in Lorraine, J., Daston and Peter Galison, *Marvelous* 2007 Book, Objectivity.

⁷Marey (1878, p. vi).

Fig. 4 One selected panel of a woolly mammoth, from the Rouffignac cave. Courtesy of the Bradshaw Foundation.

Marey was also giving voice to the movement away from the sorts of subjectivity that had characterized prior science in support of the more modern drive toward objectivity. Although some cried out for the “insights of dialectic,” “the power of arguments,” and the “flowers of language,” their protestations were lost on Marey, who dreamed of a wordless science that spoke instead in high speed photographs and mechanically generated curves; in images that were, as he put it, in the “language of the phenomena themselves”.

The first soaring national debt plot—William Playfair’s iconic 1801 graphic

Fig. 6 is one of the most remarkable displays ever produced, containing a mixture of data and design innovations to provide a convincing visual argument that connected wars and debt. The design begins with the recognition that the grid of a plot serves the same purpose as the scaffolding that workers erect to construct a building; and just as the scaffolding is removed after the building is completed, so too should the graphical gridlines. Playfair recognized that no one is likely to be interested in what happened in 1700 or 1710 or 1720, but instead interest on specific dates would arise in two different kinds of situations:

Fig. 5 Marey (1878) graphical train schedule, showing all trains between Paris and Lyons each day.

Fig. 6 The first “Skyrocketing National Debt” plot containing a lot of explanatory collateral information brilliantly integrated (Playfair’s Atlas, Plate 20).

- When the outcome one sees in the data suggests a question, e.g., what happened in 1730 or in 1775 to make the debt suddenly rise? Or in 1748 or 1784 when the debt fell or stabilized?
- When a plausibly impactful event occurs and we want to know what were its consequences on national debt, e.g., did the accession of Queen Anne in 1701 or that of George the second in 1727 have any effect?

With this idea in mind Playfair built the graph shown in Fig. 6. He then replaced the grid that he used to construct it with gridlines at interesting times. The vertical grid was no longer spaced equally across the century, and each vertical line is annotated with a plausible causal event.

We see that national debt increased in 1730 when the Spanish War began and dropped in 1748 when it ended; it jumped markedly in 1755 at the beginning of the Seven Years War and dropped in 1762 at its end (and the accession of George the third), it jumped in 1775 when the American War began and abated in 1784 when the war ended. The message is clear; wars are bad for national debt.

Last, Playfair obviously understood that perception of the data is easily manipulated by the ratio of the width of the graph to its height—the aspect ratio. The determination of this ratio is entirely subjective. If the horizontal axis is much larger than the vertical scale a soaring mountain can be transformed to a gradual plain. To make his point about the soaring national debt more emphatically, Playfair chose to make this plot higher-than-wide.

Modern research on effective design⁸ reveals that the arbitrary choice of aspect ratio is most often best resolved by selecting a ratio that makes the plot as close to a diagonal line as possible. Playfair's prescient design adhered to this advice even though the experimental evidence that revealed this result lay almost 200 years in the future.

Hybrid displays: combining type 1 and type 2 displays

Maps, which date back at least 4000 years, are among the oldest and most widely used of Type 2 displays. Their development isn't surprising, for it is a natural metaphor to represent space as space. But adding a third variable onto a geographic background is a more recent innovation. Of course, there were partially thematic maps (in China) as early as 164 BC, but the additional variables plotted were geographic variables such as altitude, which were ancillary to the main purpose of the map. A thematic map whose focus was primarily on the other variable did not appear until the 17th century.

The initial variables plotted on a geographic background were physical variables such as magnetic phenomena, currents, and geology. Such maps have obvious and immediate uses. Edmond Halley published what is believed to be the first meteorological chart in 1686. And, in 1815 William Smith (1769–1839) prepared a map depicting the geology of England that showed specific fossils were always found in corresponding layers of rock. This severely conflicted with the biblical interpretation, in which the rocks were laid down during the Great Flood. Smith's production has been called the "map that changed the world," instigating changes in thinking so that by the end of the 19th century, geology was—at least in terms of chronology and identification—advancing as a modern, evidence-based science.

The gathering of what might be called social statistics is often dated from John Graunt's 1662 analysis of the London Bills of Mortality. Graunt analyzed and published birth and death data collected by London parishes, but there were no graphs or maps included in his collection. John Arbuthnot (1710) famously used Graunt's data to illustrate his invention of null hypothesis testing, but he too did not include any graphs. In fact, the clerical errors in Arbuthnot's paper provide strong evidence that he never graphed the data. If he had prepared such a plot, the errors would have stuck out (literally) like sore thumbs and been corrected. That they weren't corrected provides support for the thesis that Arbuthnot never looked at Graunt's data in this way.

There were bits and pieces of graphic display of social data in the late 17th and early 18th centuries. Most notably, Christiaan Huygens drew a survival graph in a letter he sent to his brother in 1669. But graphs of social (economic) data only entered the scientific mainstream in 1786 with the publication of William Playfair's *Atlas*.

Playfair prepared wonderful, elegant graphs of economic data, but no maps. So far as is known, few maps of such social subjects as population, religion, or industrial production appeared before 1820. The preparers of the earliest such maps merely wrote the statistic of interest on the map.

An example of this practice is Wyld (1815) map, "Chart of the World Shewing the Religion, Population, and Civilization of Each Country." But such maps only barely "qualify as thematic since they do not graphically portray the character of the distribution effectively" (Robinson, 1982).

While it is surely true that putting numbers on a map to indicate the location where something is happening conveys more information than would merely listing them in a table, such a practice does not use the graphic medium at anywhere near its capability. This changed in 1830, when Frère de Montizon produced a map showing the population of France in which he represented the population by dots, each dot representing 10,000 people. Although no one remarked on it for the better part of a century, it remains perhaps the most important conceptual breakthrough in thematic mapping (Fig. 7).

After Montizon's map, there were a number of others that used shading to convey population between the years of 1830 and 1845. Often, they were roughly drawn and clearly meant to be of only secondary importance to the document in which they appeared. But a few were clever, remarkably polished displays. Exemplary among these were the population maps designed and prepared by Henry Drury Harness, a young lieutenant in the Royal Engineers that appeared in an 1837 *Atlas* that accompanied a report prepared by railway commissioners.

In 1847, a 34-year-old barrister named Joseph Fletcher published the first of several long papers. This paper was filled with tables and a single, rudimentary map. In fact, he rejected the use of maps explicitly, suggesting you could get all you needed by simply

⁸Cleveland (1994).

Fig. 7 Frère de Montizon's 1830 map of the population of France using irregularly spaced dots to convey population density. Original at the Bibliothèque Nationale. This one taken from Robinson (1982, p. 112).

perusing the columns of numbers and thus avoid the bother and expense of drafting and printing maps. He reversed himself completely⁹ two years later in two articles with the same title (but much greater length) as his 1847 paper. These included many shaded maps that were innovative in both content and format. Format first.

Fletcher, having a background in statistics, or at least what was thought of as statistics in the mid-19th century, did not plot the raw numbers, but instead their deviations from the mean. And so, the scale of tints used varied from the middle. This approach is common now. For example, Andrew Gelman—in *Red State, Blue State, Rich State, Blue State*—uses increasing saturations of red to show the proportion of voters who voted Republican in states where they were the majority and increasing saturations of blue for those states that voted Democratic. The closer the vote came splitting 50:50, the closer the shading was to white, regardless of the final outcome.

But, in 1849, this format was new. The advantage of centering all variables at zero was that it allowed Fletcher to prepare a number of maps, on different topics and scales, and place them side-by-side for comparison without worrying about the location of the scale. He also oriented the shading, as much as possible, in the same way. In his words, "In all the maps, it will be observed that the darker tints and the lower numbers are appropriated to the unfavorable end of the scale."

Of course, with variables such as population density, it is hard to know which end is favorable. He chose lesser population as more favorable because, we speculate, it seemed to accompany favorable outcomes on the other variables.

Although many of Fletcher's innovations in format were noteworthy, it is the content he chose that makes him special. He did not make maps of obvious physical variables such as wind direction or altitude, or even the distribution of the population (although he did make one map of that for comparative purposes). No, he had more profound purposes in mind. Joseph Fletcher made maps of moral statistics and opposed these maps with others to suggest causal interpretations to his viewers.

For example, juxtaposed next to his plot of "Ignorance in England and Wales" (Fig. 8), he also had maps of the incidence of crime (Fig. 9). He opted for this juxtaposition on the basis of detailed analysis of subsets of the data. For example, he wrote, "We thus find that the decline in total ignorance to be slowest in the most criminal and the most ignorant districts ..."

And then, looking into the phenomenon at a more microscopic level, he observed:

⁹Ordinarily, it would be hard to know exactly what it was that got Fletcher to change his approach so completely, but an evocative hint was provided in his 1849 paper when he states, "A set of shaded maps accompanies these tables, to illustrate the most important branches of the investigation, and I have endeavored to supply the deficiency which H.R.H. Prince Albert was pleased to point out, of the want of more illustrations of this kind."

Fig. 8 Ignorance in England and Wales taken from [Fletcher \(1849b\)](#).

The two least criminal regions are at the opposite extremes in this respect (the Celtic and the Scandinavian), with this important difference, that in the region where there is the greatest decline of absolute ignorance among the criminals (the Scandinavian), there is not one-half of the amount of it in the population at large which exists in the other

In addition to these maps, he also produced parallel plots of bastardy in England and Wales, improvident marriages, persons of independent means, pauperism, and many other variables that could plausibly be thought of as either causes or effects of other variables.

His goal in doing this was to generate and test hypotheses, which might then be used to guide subsequent social action and policy. His epistemological viewpoint was both wise and surprisingly modern. It is fitting that we close with three sentences of his on the use of the data and his maps (note the similarity to Richard Feynman's views quoted earlier):

The man who studies society, however, labors under a great difficulty in being entirely denied the use of experiment, and limited most rigidly to observation; the observation of elements most subtly combined, in a state of unceasing change, and wholly beyond his control. Analysis, therefore, in the sense of the chemist, is absolutely impossible; but by exhaustive enumerations of facts, which are strongly indicative of the existence of many others, or are their invariable concomitants, we get a means of detecting the excess or deficiency of certain social elements in definite classes or localities; and by multiplying these lines of observation, and the combinations in which they are arranged for purposes of comparison, we gradually arrive at higher and safe inductions, which will sometimes corroborate principles which we have reached by deductive reasoning from the moral elements of individual character, and by observations on society in the limited field of our person experience, and at others will present irreconcilable results, which the bigot of theory will despise, but which the man of science knows how to prize as gems. He who seeks facts merely to illustrate a hypothesis in which he believes with a blind faith, will throw them away in disgust; but he who uses a hypothesis merely to discover truth, will, on the contrary, abandon its use in the moment that he arrives at acts which resist all efforts to reduce them into accordance with them.

More than just facts: graphs as poetry

So far, we have portrayed visual displays of empirical information as compact summaries that, at their best, can clarify a muddled situation. This is true, as far as it goes, but omits the magic. In this section we will show how the visualization of important data can be an alchemist that can make good scientists great and transform great scientists into giants.

Fig. 9 Crime in England and Wales taken from Fletcher (1849b).

In this coda we argue that sometimes, albeit too rarely, the combination of critical questions addressed by important data and illuminated by evocative displays can achieve a transcendent, and often wholly unexpected, result. At their best, visualizations can communicate emotions and feelings in addition to cold, hard facts.

The American poet Robert Frost [1874–1963] famously pointed out that:

Poetry is when an emotion has found its thought and the thought has found its words.

We can reverse the idea, inferring that one goal of the poet is to present the words that will engender the emotion.

The communication of an emotion is a difficult task that is a goal of many other means of communication. Surely music is the most obvious; in his *Ode to Joy* Beethoven transformed his emotions through his ideas to music. The listener starts with the music and ends with exaltation. Visual artists have long followed this same path; Picasso transmitted his grief for the hundreds killed in the April 1937 bombing of the Basque town of Guernica during the Spanish Civil War in his mural *Guernica*, completed just two months after the bombing. For the receptive viewer “the emotion is so lacerating that the next step beyond would be either insanity or suicide.”¹⁰

Not all music is as transformational as *Ode to Joy*, nor are all paintings as evocative as *Guernica*; and most sequences of words are not poetic. But, happily, by Frost’s definition, there have been poets in many media, and we can rejoice in their accomplishments. Goethe’s observation that “Architecture is frozen music” suggests we might find the soul of a poet in many architects. One undeniable example is Maya Lin, whose design for the simple chronological carving of 57,661 fallen soldiers’ names into polished blocks of black granite yielded the heart-rending Vietnam Memorial in Washington DC.

We can include some databased graphs in this elite company—graphs whose impressions on the viewer are so evocative to fully deserve the adjective “poetic.” To reach this level requires a combination of data that have impact and a design of compact clarity. Reaching back to Frost’s definition, it happens when an emotion has found its data and the data have found their design.

¹⁰Mumford (2000, p. 12).

As should be obvious, a data display can only achieve this transcendent property when the data are worthy. Consider the formally competent plot shown in Fig. 10, that shows the fluctuating preferences for three flavors of ice cream in NJ over the past 30 years. It is both informative and instantly forgettable.

Now, consider an identical plot in Fig. 11 with the labels changed to reflect what the data actually were, augmented with one plausible causal covariate (the president during the time periods indicated).

The responses to this plot that we have received so far, have led us to conclude that it is difficult, if not impossible, to avoid making some causal conjectures and to immediately begin looking for other sources of data to confirm or reject those conjectures. Those conjectures arose with considerable affect. Obviously, it wasn't the graph, it was the data; the graph was the *intermediary between information and understanding*.

Let us begin slowly, by first introducing one graphic poem that might otherwise be overlooked because of its plain appearance. Then we introduce two giants in their respective fields: Charles Joseph Minard, whose use of flow maps to communicate the horrors of war defied the limitations ordinarily associated with pen and ink, and W.E.B. Du Bois, who dedicated his long career to the difficult task of improving the lives and circumstances of African-Americans. He did this by broadly communicating more than a century of African-Americans' accomplishments despite their near-universal suffering under the yokes of slavery and racism. After this introduction to these men and their work we describe a plausible result of a *gedanken* collaboration between them.

One plain graphical poem

The conductor Ignat Solzhenitsyn, in a prelude to an all-Mozart concert, made the surprising observation, "*Mozart's music is often underestimated because it is so beautiful.*" Similarly, the poetry in some graphic designs is often unappreciated because those designs are so mundane. Few graphic artists have Picasso's or Maya Lin's eye, but we ought not be blind to poetry from others with less refined skills.

The Kovno Ghetto

During the Nazi occupation of Lithuania the Nazis initiated a series of actions that resulted in the deaths of over 136,000 Jews. Initially, the Germans, in elaborately illustrated reports, meticulously documented these murders, but their production of records was reduced as the war continued. Indeed, in October of 1943, SS chief Heinrich Himmler, in a speech to his subordinates, rationalized the minimized record keeping, saying, "This is an unwritten and never-to-be-written page of glory in our history." Nonetheless, the Nazis did create some documents that tabulated what they considered their triumphs, and others also kept records of their atrocities.

In many ghettos, Jewish leaders organized committees to keep official chronicles of daily life. Indeed, from the outset of the establishment of the Kovno Ghetto, Elkhanan Elkes, chairman of the Jewish council (the *Ältestenrat*), asked Kovno's Jews to write their own history as a legacy for future generations. Artists drew pictures, writers wrote stories, musicians composed music, poets wrote verse. They all used the skills and talent that they had to record both facts and emotions for a posterity and an audience that they feared they would not be able to meet directly. Ghetto residents without such artistic talent used whatever skills they had. Those with scientific training recorded data and presented them in a variety of formats, tabular and graphical.

Fig. 12 is one of those graphs, a traditional population pyramid, whose familiar simplicity and apparent banality belie its horrifying content. The bars represent the number of Jews in the ghetto by age, youngest at the bottom. The left side represents males, the

Fig. 10 Preferences for three flavors of ice cream in NJ from 1988 to 2018.

Fig. 11 The rates per 100,000 of bias crimes in NJ from 1988 to 2018.

right females. The total length of each bar is the number of inhabitants of the ghetto of that age and sex in the beginning of October 1941. The shaded portion represents those still alive in November, only a month later.

The graphic poetry of Charles Joseph Minard

Charles Joseph Minard [1781–1870] had a long and productive life. But official regulations forced him to retire from his long-held position at the National School of Bridges and Roads on March 27, 1851, his 70th birthday. Nevertheless, he continued working and teaching for the remainder of his life. The liberty he enjoyed in retirement allowed him to devote himself to projects he had

Source: [Braun and Wainer \(2004\)](#).

begun earlier but that had been interrupted by the obligations of his job. Freed of other responsibilities, his development of new graphic forms and themes nearly doubled in rate for 20 years, and continued up to his death at age 89.¹¹

Fig. 13 is Minard's justly famous map of Napoleon's Russian campaign, in which the initially mighty metaphorical river of the 422 thousand men of the French Grand Army begins on the left by crossing the Nieman River into Russia, it gradually diminishes and is juxtaposed with the trickle of the surviving 10 thousand returning at the end. When the French army reached Moscow in October of 1812 with only 100,000 men, the moment captured at the far right of Minard's map, they found it sacked and largely deserted. They turned back and marched across the steppes into the teeth of the Russian winter—Minard coupled the returning march with the descending temperature, shown in an accompanying panel below the map. He used the falling temperature as one plausible causal variable to connect the decline of the army's size with something in addition to the sniping of Russian soldiers. When this graphic was first published, the French physiologist and chronophotographer E.J. Marey¹² [1830–1904] was in awe, saying that it “defied the pen of the historian by its brutal eloquence.”

What was the inspiration for Minard's graphical poetry? Minard's personal history makes the source clear. As a young engineer in Anvers in 1813, he had witnessed the horrors of war in a siege by the Prussian army. In his 89th year, 1869, he was deeply troubled by what he foresaw as an inevitable new war with Prussia and the havoc that it would wreak on the Second French Empire. His “figurative map” of Napoleon was published on November 20, 1869.

Minard's fears proved correct. The Franco-Prussian War began on July 19, 1870. France was ultimately defeated, and, following a long siege, Paris fell on January 28, 1871. Minard foresaw this too and, though now infirm and requiring crutches, he left Paris for Bordeaux on September 11, 1870, leaving behind nearly all his books and papers. He carried with him only a few works-in-progress, but these apparently have been lost. Sadly, six weeks later he contracted a fever, and on October 24, 1870, he died.

Very little of Minard's personal life is known; the main historical source is the obituary written by his son-in-law, Victor Chevallier in 1871.¹³ He said, “Finally, ... as if he could sense the terrible disaster that was about to disrupt the country, he illustrated the loss of lives that had been caused by ... Napoleon The graphical representation is gripping; ... it inspires bitter reflections on the human cost of the thirst for military glory.” This may well be the reason that this graphic story has become the iconic example of Minard's graphic poetry.

Using graphs in a narrative argument

Using a series of graphical displays to construct an empirical narrative was not common in Minard's time. More often, a single display was used to convey a single idea. Napoleon's March (Fig. 13), as breathtakingly marvelous as it is, is still a short story,

Fig. 13 Napoleon march graphic: Charles Joseph Minard's narrative map of Napoleon's disastrous 1812 Russian campaign. The width of the orange “river” is proportional to the size of Napoleon's invading army; its black continuation shows the size of the returning army. ¹¹See Friendly (2002) for a timeline of Minard's works.

¹²This is the same Étienne-Jules Marey we met previously when we discussed his well-known and easy-to-use graphical schedule for all trains between Paris and Lyon shown in Fig. 5.

¹³V. Chevallier, Notice nécrologique sur M. Minard, inspecteur général des ponts et chaussées, en retraite, Annales des ponts et chaussées, 2 (1871), 1–22. An English translation was prepared by Dawn Finley, <https://www.edwardtufte.com/tufte/minard-obit>. For further detail on Minard's life, see Friendly (2002) and a biography, <http://datavis.ca/gallery/minard/biography.pdf>.

with the limitations commonly associated with that form. Embedding a sequence of displays in an empirical narrative has been too rarely used. But when used effectively, this approach forms a memorable image that has remarkable impact.

Minard himself sometimes used comparative graphs to tell a story. As one example, he prepared a sequence of plots to show how the Union blockade of Confederate ports during the American Civil War affected the supply of cotton to English mills. In Fig. 14 we reproduce his three-part plot (for 1858, 1864, and 1865) which made it clear that before the US Civil War the southern US states were the principal supplier for British mills. But when that supply was effectively cut off by the blockade, the mill owners replaced it with cotton from India and Egypt, which continued, at a slightly diminished level, even after the war had ended.

Arguably, the most famous (and perhaps the first) use of a coordinated sequence of displays to complement an integrated verbal explanation was Leonardo's magnificent tale (Fig. 15) of how a human fetus is carried in a womb. It challenged Galen's 1400-year-old description of the human womb as bicameral (having two sinuses) to carry multiple births.

W.E.B. Du Bois

William Edward Burghardt (W.E.B.) Du Bois was born in Great Barrington, Massachusetts on February 23, 1868, shortly after the end of slavery in the United States. He died in Accra, Ghana on August 27, 1963. During the course of his 95 years he accumulated an extraordinary list of accomplishments. He earned a Ph.D. from Harvard—the first African-American to do so. He was by turns a sociologist, historian, civil rights activist, and author. His many books included: *The Souls of Black Folk*, *The Suppression of the African Slave Trade*, *Dusk of Dawn*, *Darkwater*, and *The Talented Tenth*. He was also a skilled data scientist devoted to the power of unadorned facts.

It is natural to ask how DuBois, more than a century ago, was able to look at numbers and extract meaning. Certainly the consensus then, and now, is that the extraction of meaning from the huge tables of numbers that might carry that meaning is wearisome to the eye and difficult for the brain; as the American economists Farquahr & Farquahr so memorably put it in 1898, it is a task akin to extracting sunbeams from cucumbers. We can plausibly conclude that DuBois was best able to read meaning from numbers after they had been transformed to visual displays. His remarkable success at this means that as a data scientist, he contributed to the development of the modern approach to constructing a narrative argument based on evidence through his use of a series of graphic displays. In this way he is a direct, lineal, descendant of Leonardo and Minard.

In 1900 Du Bois collaborated with Booker T. Washington on "The Exhibit of American Negroes" at the Paris World Fair (the *Exposition Universelle Internationale*). It included 400 patents by African-Americans as well as 200 books with African-American

authors. In addition, a large number of facts about African-Americans were woven into a memorable narrative by transforming them into data graphics.¹⁴

The nearly 60 graphs and thematic maps spanned a wide range of characteristics of African-Americans and their lives. This section of the exhibit was titled "A series of statistical charts illustrating the condition of the descendants of former African slaves now in residence in the United States of America."

Du Bois began his story with a graph dramatically showing the profound effect of Lincoln's Emancipation Proclamation (Fig. 16). It shows the balance of enslaved versus free African-Americans from 1790 until 1870. From this we learn that the proportion of free African-Americans during slavery hovered around 12% of the total African-American population until January of 1863, when Lincoln's Emancipation Proclamation¹⁵ was the key to the dramatic change shown.

Having established the status of African-Americans in the United States, he then used a simple bar chart (Fig. 17) to show that there were seven-and-a-half million African-Americans in 1890 and also the exponential growth of that population over the prior

¹⁴Du Bois's account of this exhibit appears in Du Bois (1900). Nearly the entire collection, comprising over 200 photographs and numerous charts and maps, has been digitized by the Library of Congress. See: <https://blogs.loc.gov/picturethis/2014/02/du-bois-american-negro-exhibit-for-the-1900-paris-exposition/>.

¹⁵Although all slaves in the Confederate States were freed by Lincoln's proclamation in 1863, it was not until the ratification of the 13th amendment on December 6, 1865 that all slavery was truly abolished in the United States.

Fig. 16 Effect of the emancipation proclamation: proportion of slaves and free Negroes from 1790 until 1870. Source: Library of Congress, <http://hdl.loc.gov/loc.pnp/ppmsca.33913>.

150 years. Although a simple time series line graph in the style of Playfair might have been used, Du Bois chose the format of a horizontal bar chart in the style of Minard to also show the exact numbers.

Du Bois used these displays to answer fundamental questions of existence: How many of us are there? Are we increasing or decreasing in number? How fast? The next obvious questions are “Where do we live?” and “Where did we come from?” He addressed the first of these in Fig. 18, which showed dramatically the heavy concentration of African-Americans in what had been the states of the Confederacy, but there were signs of a movement out of the Deep South into the Northeast. He addressed the second question (Fig. 19) with the very first display of his exhibit, showing the sources and destinations of the slave trade.

He continued with 53 other plots, expanding and enriching the narrative. This fact-based description was made possible by the 1870 expansion of the US census, which, for the first time, included the African-American citizens in the national accounting.

Absent, however was any sort of coherent representation of the gigantic migration of African-Americans out of the South that took place after Reconstruction and continued for the first half of the 20th century. This phenomenon could have been beautifully communicated with a collaborative effort between Du Bois and Minard.

The Great Migration

As we have seen in Figs. 17 and 18, there were 7.5 million African-Americans in 1890, the great majority of whom lived in the rural south of the United States. Between 1916 and 1970 more than 6 million had migrated to the industrial North and West. Historians have dubbed this the Great Migration, commemorating it as the largest peacetime movement of people within a country in history.¹⁶

Such a movement cries out for description and explanation. The biggest initial question is, of course, “Why?” But before one can tackle such an interpretative question, one faces the descriptive questions: “From where to where?” “When?” and “How Many?” These questions are fully answered with data, indeed, the sorts of data that are routinely and rigorously gathered by the U.S.

¹⁶Lemann (1991).

Fig. 17 Du Bois's bar chart: increase of the Negro population of the United States from 1750 until 1890. Source: Library of Congress, <http://hdl.loc.gov/loc.pnp/ppmsca.33901>.

decennial census. But extracting geographic structure from the entangled tables of numbers describing it brings to mind the cucumbers of the brothers Farquahr. And communicating the messages contained in these census tables beyond the eyes of experts is far better done graphically. But how are we to transform the tables to graphs?

To answer this question we adjoin the life work of the two giants whose work forms the center of this article: Du Bois's passion for improving the lives of African-Americans and widely communicating their accomplishments, and Minard's genius for transforming complex data into compelling pictures that impacts both the intellect and the emotions.

Although their long lives overlapped by but two years (and even during that brief period they were separated by language, culture, and an ocean) the work and goals of Minard and Du Bois were complementary. In the balance of this article we demonstrate of how a blending of their work yields an evocative narrative of such awakening power that it can rightfully be described as poetic.

The census has always been tasked with counting all residents of the United States; in 1863 its' scope was expanded to include those African-Americans who had been emancipated from slavery. Thus, the 1870 census, just after the Civil War, included counts of African-Americans for the first time.¹⁷ The census data provided counts, by race, place of birth and place of residence, making it straightforward to study migration patterns of people.

The newly freed African-Americans faced impossibly difficult times. They were desperately poor, largely illiterate, and living in a region whose plantation economy offered little chance for improvement. Most worked as sharecroppers, tenant farmers, or farm laborers. In addition to economic woes, the post Reconstruction South was racist and violent: Jim Crow laws instituted *de jure* racial segregation, and racist organizations like the Ku Klux Klan, the White League, and the Red Shirts made terror a part of daily life for African-Americans living in the post-Civil War Confederate South. Thus, it isn't surprising that large numbers of African-Americans opted to migrate to the North for greater opportunities. World War I created a huge demand for workers in northern factories; northern railroads needed workers so badly they provided free train passes for thousands of southern blacks.

¹⁷Previously the census included slaves as merely counts within various categories (e.g., age and sex) as part of the household goods of their owners.

A gedanken collaboration

Let us now imagine a collaboration between Du Bois, who chose the topic on which we focus our attention, the Census, which supplied the data, and Minard, who invented and perfected the graphical method that would allow us to see the character of the Great Migration, which, over the 55 year span from 1915 until 1970 saw more than six million African-Americans leave the South.¹⁸

Shown in **Fig. 20** is a compound plot of four flow maps drawn in the style of C.J. Minard. The four panels are spaced 20 years apart, showing the movement of non-whites (the census designation, which consisted primarily of African-Americans). The arrows show the net migration (outflow MINUS inflow), and the widths of the arrows are proportional to the number of migrants. The panel at the bottom depicts the annual number of lynchings of African-Americans; 94% of these were in the former Confederacy. We are using this variable in the same way that Minard used temperature in his map of Napoleon’s march—as one possible causal variable.

The left-most panel of **Fig. 20** (for 1880) shows the beginning of the post-reconstruction exodus. Most of the migrants left the South for the industrial cities of the North and Northeast (Chicago, Detroit, Pittsburgh, D.C.). The number of lynchings increased, peaking in 1890, and in 1900 the migration more than doubled. The need for labor expanded during World War I and is manifested by the further increases shown in the 1920 panel, when 454,000 left the South in the decade 1910–1920, and the 1940 panel, when another 1,500,000 left during the Depression and the build-up to World War II. Another principal cause of this part of the migration was the great Mississippi Flood of 1927, in which more than 200,000 African-Americans were displaced from their homes on the lower Mississippi River.

The Great Depression affected huge numbers of people, both White and Black, many of whom lost their homes (particularly in the Dust Bowl states) and left for a better life elsewhere. This is shown for African-Americans in the top panel of **Fig. 21** (an enlargement of the 1940 panel of **Fig. 20**). The bottom panel (1940 data for Whites) provides a dramatic contrast. Although African-Americans fled the South in the decades of the Great Depression in much the same patterns as they did in the decades before and after, the

Whites were often farmers whose economic lives were ruined by the Dust Bowl catastrophe (think of the Joads in Steinbeck's *Grapes of Wrath*, who piled all their belongings onto the family truck and headed West to California).

Conclusion

So we beat on, boats against the current, borne back ceaselessly into the past.

Nick Carraway's haunting last line from F. Scott Fitzgerald's *The Great Gatsby*.

This article, in a very real sense, provides a history and framework for modern science. We have found that, whenever we face a new problem it is always wise to look backward first; this provides the benefit of helping us to understand the thinking of those who have preceded us. The hubris that drives some to believe that we are wiser than our forebears rarely yields a happy result. This article is driven by the belief that we are best prepared to move into the unknown future by better understanding the past. In addition to illuminating the past, we wished to draw attention to the extraordinary power of visual depiction of quantitative phenomena to communicate efficiently both facts and emotion—how a graph can be a poem.

To illustrate these points, we have provided a portrait of the Great Migration of African-Americans from the South of the United States in the century following their emancipation from slavery. Sensible space limitations forced us to make some simplifications. In doing so we found that Mies van der Rohe's dictum "less is more" was spectacularly true and faced some of the same choices for level of detail vs. fidelity that Du Bois and Minard encountered in their work.

Looking at decade-by-decade plots added little that was not more clearly shown by collapsing to 20-year periods; showing migration destinations to the nine census regions, rather than the four super-regions we constructed added more noise than structure; including a 1960 plot that contains the final stage of the exodus, when almost 3.5 million left the South for the North and the West adds quantity to what we have already shown, but does not change the overall message. Thus, we believe that this summary is both accurate and complete, and provides a suitable continuation of the task that W.E.B. Du Bois began more than a century ago.

Du Bois's graphical narrative showed facts about African-Americans; how they started out and what they became. We added some details of how they got there and where they came from. The tool we chose to do this we snatched from the past, mining the ideas of the great C.J. Minard. We shamelessly borrowed his metaphor of the flow of goods or people across a geographic background. Minard's adjoining the delicate curve of declining temperature with the rapid shrinkage of Napoleon's army in their death march across the Russian steppes in the winter of 1812 forces the viewer to share the great sadness that enveloped all of France. Our use of the ancillary variable of lynchings was meant to generate a similar emotion, as one empathizes with the terror that African-American southerners must have felt as they made the decision to leave their homes and seek to rebuild their lives elsewhere.

It doesn't take an excessive amount of imagination to connect this same methodology to the Jewish diaspora from Nazi Germany, or the Hebrews from Pharaoh's Egypt, or peasants during the eastern European pogroms, or the Cherokees' Trail of Tears, or the Bataan Death March. We will leave it to others to prepare graphic accounts so that we can better understand and remember the facts and the emotions of these tragic events. For poetic data visualizations, combining both the communication of facts that can be learned, with emotions that can live in your heart forever can help provide a bulwark against future horrors, for "*there is a magic in graphs. The profile of a curve reveals in a flash a whole situation—the life history of an epidemic, a panic, or an era of prosperity. The curve informs the mind, awakens the imagination, convinces.*"^{19,20}

We begin by introducing the idea of meta-analysis. We then present the steps in the process of conducting a meta-analysis of summary data, with special attention to statistical analyses. We illustrate each step using recent meta-analyses of studies of

game-based instruction for second-language learning. We also briefly mention advanced meta-analysis techniques including multi-variate meta-analysis and Bayesian meta-analysis.

What is meta-analysis?

Meta-analysis, or the “analysis of analyses” is a term created by [Gene Glass \(1976\)](#). Meta-analysis is the systematic accumulation and analysis of results from series of studies addressing a common question. Glass was motivated to coin this term and create procedures for summarizing results by the vast numbers of disparate empirical studies on the use of psychotherapy. He wanted to statistically analyze the large set of results on psychotherapy, and integrate them in a more rigorous fashion than he could achieve with a traditional narrative review. Meta-analysts assess typical study findings and also explore why findings vary across studies. Many scholars use the word “meta-analysis” to mean the entire process of integrating results of related studies, whereas others use the terms research synthesis, integrative review, or systematic review for this purpose. We use the term in the broader sense in this chapter.

Glass revolutionized the synthesis of treatment studies by using effect sizes to represent study findings. An effect size is an index that is comparable across studies and captures information about the research question of interest. Effect sizes may not be needed if complete data sets are available, as in individualized-participant-data (IPD) meta-analysis ([Cooper and Patall, 2009](#)). The term effect size often refers to the standardized mean difference, but many other indices (correlations, proportions, etc.) can serve as effect sizes in meta-analyses. (Effect sizes are discussed further below.)

Glass’s first meta-analyses concerned the effectiveness of psychotherapy and the impact of class size on student achievement, and he used a standardized mean difference as the effect size, specifically

$$g_i^G = \frac{(\bar{Y}_i^T - \bar{Y}_i^C)}{S_i^C}, \quad (1)$$

where $\bar{Y}_i^T$ is the mean of the treatment group in study i on some outcome Y , $\bar{Y}_i^C$ is the analogous mean from the control group, and S_i^C is the standard deviation (SD) of Y for the control group in study i . This index resembles a z score, except that its numerator is a difference between means, not the difference between a score and a mean. Thus g_i^G can be interpreted as the number of standard deviations of difference between the two group means, in the control-group’s score scale. The population analogue to g_i^G is the parameter $\delta_i^G = (\mu_i^T - \mu_i^C)/\sigma_i^C$ where μ_i^T and μ_i^C are the treatment and control population means, respectively, and σ_i^C is the SD of the control population.

Meta-analyses have the same components as primary research ([Jackson, 1980](#); [Cooper, 1982, 1989, 2017](#)). A simple version of Cooper’s steps in the meta-analysis process includes:

1. Problem formulation, or the crafting of a clear question about a relationship, group difference, or other effect that typically specifies which study characteristics may explain patterns of results across studies;
2. Literature search, where a systematic search of the literature uses explicit rules to identify relevant studies;
3. Data evaluation, including calculation of effect sizes and extraction of study features as well as ongoing evaluation of study relevance;
4. Data analysis, where statistical techniques are used to relate effect sizes to features such as sample characteristics, treatment intensity, methods of study, etc.;
5. Interpretation of synthesis results, to translate the results; and
6. Public presentation, via published manuscript or some other form of report.

Other descriptions of the process use different labels for these steps or add steps.

Problem formulation

A successful meta-analysis is based on specific questions that are not so broad as to be unanswerable, or so narrow that few studies address them. Consider the question “Does the use of educational technology improve learning?”. Many kinds of technology exist, and it is likely they do not all work for all students or all kinds of learning. We may want to specify a content area (e.g., math learning or second-language acquisition), and perhaps an age level or range of grades for the learners. Should the focus be narrowed, to mobile learning or game-based interventions? Should we study learning inside or out of school? Each consideration allows the meta-analyst to narrow or broaden the scope of the review and the degree to which its conclusions can be generalized.

Theory and frameworks in problem development

Relevant theory, a practical framework, or a scoping review can support good question development. Prior reviews (if any) and scoping reviews ([Munn et al., 2018](#)) can identify how many studies exist, clarify constructs examined therein, and possibly identify gaps in knowledge in a domain.

A general framework such as [Cronbach's \(1982\)](#) UTOS framework for generalizability may also be useful. UTOS stands for Units, Treatments, Outcomes (originally "observing operations"), and Settings. Specifying each of these limits the domains to which meta-analysis inferences may apply. In medicine the PICO framework (for Patient/Problem, Intervention, Comparison, and Outcomes; [Richardson et al., 1995](#)) has become a popular way to develop "well-built" questions ([1995](#), p. A12). [Becker \(1996\)](#) and [Matt and Cook \(2009\)](#) have applied the UTOS framework to the meta-analysis context. [Becker \(1996\)](#) pointed out that the factors that lead to differences in study results often reflect the units, treatments, etc., that were studied. These may be dictated by a theory of an intervention, a model of interrelationships, or practical considerations.

Attributing differences in study results to characteristics of treatments, participants, or settings is a key part of a meta-analysis. Considering these components up front focuses the literature search, study screening, data extraction, and analysis. Selecting these features is both a conceptual and practical task. At the theoretical level one must first define the constructs of interest – such as language learning in our example. Then the meta-analyst must operationalize those constructs as part of defining inclusion rules. Clear operationalization is important not only for outcome constructs (e.g., tests of language skill), but also for treatments (e.g., What kinds of learning games should be examined? What components must they include?) and other predictors. This task can be challenging when reviewing studies of complex interventions ([Higgins et al., 2019](#)), or when many factors influence the outcomes of interest (e.g., [Brown et al., 2016](#)).

The degree to which the meta-analyst wants to generalize beyond their collected studies also determines what statistical models should be used. If a meta-analyst only wants to make inferences about the studies at hand (i.e., does not wish to generalize) the fixed-effect model can be used. Fixed-effect models are also appropriate when all studies share a common parameter value, or when a set of predictors explains all of the variation in the study outcomes ([Hedges and Vevea, 1998](#)). In contrast random-effects models assume that the true effects vary across studies and are sampled from a theoretical population of parameter values. In spite of the fact that the studies in meta-analyses are rarely randomly sampled, random-effects models are very common in current practice. Other details of these two models are discussed below.

Inclusion and exclusion rules

Inclusion and exclusion rules developed in the problem-formulation stage help the reviewer define the limits of the search (useful at step 2), and of later generalizations. Setting criteria for participant characteristics, intervention features, methods used, and publication-date limits can contract the size of the relevant literature and ensure that collected studies will be useful. Using too many exclusion rules may lead to very small sets of studies; here scoping reviews can help in planning the details of the meta-analysis.

The nature of the question asked determines which effect sizes should be used. Questions typically imply a target effect size that requires certain data (e.g., means and SDs, correlations); these can be listed in the inclusion rules. Whether the target effect size can be calculated in all studies depends on what is reported. Differences in methods used in primary studies, such as the presence or absence of a control group, or the type of sample used, affect what can be computed as an effect magnitude and impact study validity. Our question on the effectiveness of educational technology did not specify whether the technology would be compared to another means of instruction (e.g., to non-technology-based instruction). However, two-group studies provide stronger causal inferences and better internal validity than one-group designs, thus bolstering meta-analytic inferences. Our question asked about improvement in learning, implying that we should collect studies of change in performance. Methods considerations like these should be specified as part of problem formulation.

Examples of problem formulation

Two examples illustrate problem formulation in meta-analysis. [Thompson and von Gillern \(2020\)](#) reviewed studies of game-based instruction for vocabulary learning. They examined only English language learners, but the native language of the learners was not restricted. Participants ranged in school level from kindergarten through college. The authors required that studies use digital video games (the T or treatment) on several platforms, versus some alternative form of instruction. Their outcome (the O) was vocabulary acquisition, and the settings were largely school based. Both experiments and quasi-experiments were included.

In contrast [Cho et al. \(2018\)](#) studied technology for second-language learning, but only on mobile devices – a different "T". Cho et al. did not require that the mobile-learning instruction involve games, and they examined a broader set of Os: vocabulary plus pronunciation skills and general reading and language-arts outcomes. They also required that all studies have a control (non-mobile) condition such as textbook- or paper-based vocabulary lessons. Last, Cho et al. included only experiments. Only one study ([Wu and Huang, 2017](#)) appeared in both reviews.

Literature search

Once a suitable problem is in hand, a thorough, unbiased, and replicable search is conducted for both published and unpublished documents. Ideally the meta-analyst will find all available sources, but that can be hampered by publication bias, discussed below. Databases should always be used in the search. Inspecting the thesaurus of search terms for each database helps identify keywords for the most effective search logic. In our view it is critical to search for dissertations and theses. They are rich with data, and while

Fig. 1 PRISMA flow chart. From Thompson, C.G., von Gillern, S., 2020. Video-game based instruction for vocabulary acquisition with english language learners: a Bayesian meta-analysis. *Educ. Res. Rev.* 30, 100332.

technically unpublished have usually been thoroughly vetted. Also, because they are not formally published, the threat of publication and reporting bias is less.

Existing reviews may also be a source of studies, depending on the overlap in the review questions and any date restrictions. Online searching (e.g., via google, google scholar, and other web sites), writing to relevant listservs, and contacting scholars active in a field can also help identify unpublished sources. For some questions that may have been of secondary importance to the original research (e.g., gender differences) it may be useful to scan issues of relevant journals for articles not tagged with appropriate key words.

Once the search is done, the titles, abstracts, or full texts of identified sources must be screened for appropriateness. This avoids wasting time extracting information from studies without data or that do not meet inclusion and exclusion rules. During this process one must track deleted studies and the reasons for their deletion so that a Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) flow chart (Page et al., 2021) can be created. Fig. 1 shows the flow chart from Thompson and von Gillern's review of game-based language-learning studies (2020, p. 5).

Meta-analysts routinely screen thousands of sources to cull out unsuitable studies. Recent advances in searching and screening techniques automate these processes. Software products such as RobotSearch and Abstrackr (Wallace et al., 2012, 2014), and SWIFT-Review (Howard et al., 2016), among others, speed the work of screening. Marshall and Wallace (2019) describe these and other tools for automating research syntheses.

Data evaluation

Data evaluation includes both data extraction and evaluation. The meta-analyst, optimally with a team of assistants, computes effect sizes to represent study results and extracts or "codes" features of the studies. These features represent variables that may relate to study results, or that one hopes do not relate to results.

Computing effect sizes

Kelley and Preacher (2012, p. 140) defined effect size as “a quantitative reflection of the magnitude of some phenomenon that is used for the purpose of addressing a question of interest”; they extensively discuss effect-size properties. The effect sizes for any meta-analysis should flow naturally from the question driving the synthesis. However, variations in study design lead to a diversity of possible effect sizes, and the meta-analyst must choose among them based on the goals of the meta-analysis and the data available. Consider our question about improvements in learning due to educational technology. Our effect size must incorporate measures of language skill taken before and after the intervention. Studies that measure language only post intervention would be useless. Preliminary knowledge of the study designs used in the domain under review will help the meta-analyst identify appropriate effect sizes.

To cover all potential effect sizes would require several book chapters, thus we mention only the most common effect sizes. Each has a standard error that can be computed with only one observed instance of the effect size. Thus, meta-analysts can conduct analyses that (1) account for each study’s uncertainty, and (2) provide measures of model fit, unlike most analyses learned in introductory statistics classes.

We use the symbols T_i and θ_i to refer to the effect size of interest in study i and the parameter it is estimating and v_i to denote the variance of each T_i . We use this notation as we introduce each of the effects in this section, and below as we discuss analyses.

Mean differences: the d family of effect sizes

In Eq. (1) we introduced the effect size used by Glass (1976) to represent average differences between two groups. Hedges (1981; Hedges and Olkin, 1985) argued that if one accepts the typical assumption that the population variances of the two groups are equal to σ_i^2 (i.e., the two-sample t -test homoskedasticity assumption), a better estimator is

$$T_i = g_i = \frac{(\bar{Y}_i^T - \bar{Y}_i^C)}{S_i^P}. \quad (2)$$

Here the denominator is the pooled within groups standard deviation

$$S_i^P = \sqrt{\frac{(n_i^T - 1)[S_i^T]^2 + (n_i^C - 1)[S_i^C]^2}{(n_i^T + n_i^C - 2)}},$$

where n_i^T and n_i^C are the sample sizes for the treatment and control groups, respectively, and $\bar{Y}_i^T$, $\bar{Y}_i^C$, S_i^T , and S_i^C are defined for (1) above. Hedges noted that in small samples g_i is a biased estimator of the population effect size $\delta_i = (\mu_i^T - \mu_i^C)/\sigma_i$. He derived the approximate unbiased estimator

$$d_i = J(m_i)g_i, \quad (3)$$

where $J(m_i) = 1 - 3/(4m_i - 1)$ and $m_i = n_i^T + n_i^C - 2$, the degrees of freedom of the two sample t test. Hedges also provided a large-sample asymptotic variance for d_i , which is

$$v_i = \text{Var}(d_i) = [J(m_i)]^2 \left[\frac{n_i^T + n_i^C}{n_i^T n_i^C} + \frac{\delta_i^2}{2(n_i^T + n_i^C)} \right], \quad (4)$$

with d_i being substituted for δ_i in practice.

Other study designs necessitate the use of different effect sizes for mean differences; Lin and Aloe (2020) provide a good overview. For example, Becker (1988) proposed an effect size for pre-post designs, $T_i = g_i^{\text{Change}} = (\bar{Y}_i - \bar{X}_i)/S_{X_i}$, where X and Y are pretest and posttest measures, respectively, and S_{X_i} is the pretest standard deviation in study i . Hedges (2011) and Lai and Kwok (2014, 2016) suggested ways to compute effect sizes for multi-level analyses. Keef and Roberts (2004) developed a partial standardized-mean-difference effect size which divides a mean difference adjusted for a covariate by the square root of the residual standard error. This latter estimator will be larger than an effect computed using Eq. (2) if the covariate reduces residual error.

The key issue for meta-analysts as they choose among the available estimators is whether effects will be comparable across studies. Sometimes effects from different designs can be combined, especially if adjustments are made to enhance comparability. For example, d values from t tests may be combined with effects from cluster randomized trials if the latter have been standardized using a measure of within-cluster variation (Hedges, 2007). Similarly, a partial standardized mean difference that controls for socioeconomic status (SES) in a broad national sample may be comparable to an effect size with no covariate control from a sample with participant SES levels in a narrow range (e.g., a low SES sample). Sometimes, though, disparate designs inform us about very different phenomena, and in such cases their effects should not be combined with the two-sample d_i above. For one, indices measuring mean change for a single group (like g_i^{Change}) are best synthesized separately from the two-sample d given in Eq. (3) and other two-group effects.

Correlational effects: r and associated measures

Another common effect size is Pearson's correlation, $T_i = r_i$, which estimates the population correlation ρ_i . Bivariate correlations are widely reported and have a simple variance,

$$v_i = \text{Var}(r_i) = \frac{(1 - \rho_i^2)^2}{n_i - 1}.$$

This variance decreases as ρ_i approaches either -1 or 1 , and extreme ρ_i produce skewed sampling distributions of r . Many meta-analysts therefore analyze the variance-stabilized [Fisher \(1921\)](#) transform of r ,

$$T_i = z_i = 0.5 \ln \left(\frac{1 + r_i}{1 - r_i} \right),$$

which has variance $v_i = 1/(n_i - 3)$. Many sources cover the synthesis of correlations, including [Field \(2001\)](#) and the writings of [Hunter and Schmidt \(2004\)](#).

Meta-analysts have also summarized partial and semi-partial correlations (e.g., [Polanin et al., 2021](#)) and correlation matrices. Methods for estimating and analyzing partial indices are covered by [Aloe \(2014\)](#), [Aloe and Becker \(2012\)](#), [Aloe and Thompson \(2013\)](#), and [Becker and Wu \(2007\)](#). Summaries of correlation matrices are now also common ([Becker, 1992, 1995](#); [Becker and Aloe, 2019](#)) as is the synthesis of data on complex models (e.g., [Brown et al., 2015, 2016](#)).

Count based effect sizes

Studies in medicine often deal with counts or percentages of patients who are ill versus healthy. [Borenstein and Hedges \(2019\)](#) give an extensive overview of available effects for such data. Count data are often analyzed as proportions or "risks" $T_i = p_i = n_{i1}/n_i$ or logits $\ln [p_i/(1 - p_i)]$, where the count of events of interest is denoted as n_{i1} and the sample size is n_i . The variance of p_i is $v_i = \pi_i (1 - \pi_i)/n_i$, which has its maximum at $\pi_i = 0.5$ but can be much smaller near 0 and 1. The logit has a distribution that is asymptotically more normal than that of p_i .

When count data arise from two groups, the meta-analyst has many options for handling the counts in a synthesis. The risk difference ($p_i^T - p_i^C$), risk ratio (p_i^T / p_i^C) (or its log, $\ln [p_i^T / p_i^C]$), or the odds ratio $[p_i^T / (1 - p_i^T)] / [p_i^C / (1 - p_i^C)]$ can be used. The log-odds ratio (LOR) is most common due to its superior statistical properties ([Borenstein and Hedges, 2019](#)). It is computed as

$$T_i = \text{LOR}_i = \ln \left(\frac{p_i^T / (1 - p_i^T)}{p_i^C / (1 - p_i^C)} \right).$$

Denoting the number of cases with the event of interest as n_{i1} and the number of non-event cases as $n_{i0} = n_i - n_{i1}$, the variance of the LOR can be computed as

$$v_i = \text{Var}(\text{LOR}_i) = \frac{1}{n_{i1}} + \frac{1}{n_{i0}^T} + \frac{1}{n_{i1}^C} + \frac{1}{n_{i0}^C}.$$

Other effect sizes

Other effect indices may be relevant for special situations. For example, one can summarize variances or their ratios, data from diagnostic tests such as sensitivities and specificities ([Chu et al., 2009](#)), or the area under the curve (AUC) index for the receiver operating characteristic curve. Survival-curve analyses (see [Combes et al., 2014](#)), models that predict risk of disease ([Debray et al., 2019](#)), and studies in genetics ([Kavvoura and Ioannidis, 2008](#)) each have their own effect indices.

We are not fans of the use of p values to represent effects, as they confound effect size with sample size. Only when commensurate indices cannot be found does it make sense to use p values.

Measurement error

A problem for many effect measures is measurement error or unreliability. Differential measurement error is a central concern in the literature on validity generalization – the synthesis of test validities (see, e.g., [Schmidt and Hunter, 1977](#)). If measures of reliability can be obtained for each study's measures, corrections can be applied. If not, other aspects of the measures used, such as test length, may be proxies for the degree of measurement error.

If $r_{YY'}$ is the reliability of outcome measure Y , a standardized mean difference d can be corrected using the formula $d^C = d / \sqrt{r_{YY'}}$. Dividing the correlation by the square root of the product of the reliabilities of both measures disattenuates the observed r . This correction always increases effect sizes, as unreliability lowers observed effect sizes and measures of association. Techniques to adjust for differential reliability (mentioned above) are sensible to use when reliabilities vary widely across studies. For further details see [Hunter and Schmidt \(2004\)](#).

Coding theoretically important variables

Features of substantive or theoretical interest should always be coded as potential explanatory variables for differences among studies. Variables capturing the type of treatment, treatment duration (e.g., [Thompson and von Gillern, 2020](#)) or intensity, or

treatment fidelity also often have theoretical significance. Meta-analyses of complex treatments may examine a set of key program components. Such study features may be correlated. Thus, the meta-analyst should check for collinearity before including multiple features as moderators. Participant characteristics such as age or grade, gender, and level of experience with content or degree of expertise (e.g., in a sport) are often coded.

Educational meta-analyses often examine tests of subject-matter content taught in an intervention, or other academic measures (such as grades), as well as psychological constructs such as motivation, attention, and the like. If the outcomes measured vary across studies, information should be coded so the meta-analyst can analyze whether mean effects differ across constructs or measures. [Cho et al. \(2018\)](#) coded four categories of language learning, whereas [Thompson and von Gillern \(2020\)](#) examined only vocabulary acquisition.

Coding study quality and methodological variables

Variables reflecting study methods and quality must be coded. Characteristics of how a study is conducted may be considered nuisance variables by some – but failing to check on their relationships to the effect size would be an error. Some methodological features will bring a critic's eye to the synthesis if left uncoded, with variables capturing risk of bias being especially critical for meta-analyses of interventions. Ignoring whether studies used random assignment overlooks a key aspect of internal validity. Similarly, failing to note the presence of attrition, confounded treatments, or evidence of group incomparability raises doubts about the quality of the synthesis. Variables like date of publication (to allow examination of time trends or changes in methods used), or author gender ([Eagly and Carli, 1981](#)) and affiliation allow for tracking of potential biases.

[Valentine and Cooper \(2008\)](#) developed the Study Design and Implementation Assessment Device which captures many aspects of quality in education studies, and very detailed risk-of-bias tools have been developed for medical syntheses (RoB2: [Sterne et al., 2019](#); ROBINS-I: [Sterne et al., 2016](#)). These tools do not fit all meta-analyses but provide key aspects of bias for meta-analysts to consider.

In our examples, Cho et al. differentiated standardized tests from researcher-made tests (which may be more targeted to the skills taught in the interventions); studies using researcher-made tests showed higher effects. Thompson and von Gillern were unable to fully code type of assessment due to poor reporting in their primary studies, but noted that about 25% of their studies used standardized instruments. These authors also coded whether each study had used random allocation to assign participants to groups. Neither meta-analysis corrected for attenuation.

Reliability of coding

The extraction of information for meta-analysis, like any other coding process, involves human judgment. Meta-analysts must enhance reliability by training their coders and providing them with clear instructions. In state-of-the-art syntheses two or more trained persons code all studies. The meta-analyst develops a coding sheet and instructions, then selects a few studies for coding practice. Coders discuss discrepancies, unusual cases, or potential additional variables before further coding. A check for coder drift, with a reliability check of each coded variable, may be done after an initial set of studies has been coded. After coding is complete, the reliability of each coded feature should be assessed and discrepancies resolved. Each feature's reliability should be reported in the meta-analysis write-up. For example, Cho and colleagues reported initial inter-coder reliabilities between .78 and 1; coder reliability was not reported by Thompson and von Gillern.

Data analysis

The data-analysis stage of the review often begins with assessments of the average size of the effect of interest, and of the degree to which effect sizes vary across studies. Variation can be estimated or tested, though initial homogeneity testing has become less common as more meta-analysts begin with the assumption that true study effects vary (i.e., they adopt random-effects models for their analyses). Statistical and graphical procedures help the meta-analyst to explore and explain the nature of their accumulated results.

Notation and initial graphics

Notation

We denote the effect size of interest as T_i , for $i = 1$ to k independent studies; each T_i estimates a parameter θ_i . The simplest fixed-effect model for the effect size within study i is

$$T_i = \theta + e_i, \quad (5)$$

where e_i reflects sampling variance resulting from the specific sample of cases examined within study i . For most common effect-magnitude indices the errors e_i are treated as approximately normal in large samples, that is, $e_i \sim \text{Normal}(0, v_i)$, for $i = 1$ to k , where v_i is the variance of the residual e_i , or of T_i conditional on θ . Under this model θ is a common effect size shared by all

populations under study. Formulas for v_i were given above. The v_i are typically treated as known, which is plausible because all v_i are asymptotically efficient, but this efficiency is not guaranteed for small samples.

Our examples use the studies of game-based instruction for second-language learning from Thompson and von Gillern (henceforth TvG; 2020). Treatment-control differences were represented with the standardized-mean-difference index $T_i = d_i$ shown in Eq. (3). Positive T_i occur when the game-based instructional group outscores the comparison group on a post-instruction language test.

Initial graphics

Because each effect size has its own standard error, a typical first step in a meta-analysis is to create a forest plot showing $100(1 - \alpha)\%$ confidence intervals (CIs; typically 95%) for the effect sizes under fixed effects using $T_i \pm z_{\alpha/2} \sqrt{v_i}$ with $\alpha = 0.05$. Either fixed- or random-effects CIs can be made, but we prefer fixed-effect CIs which give a better picture of the degree of between-studies variation because only within-study variation is captured in the CI bars.

Forest plots provide information on central tendency and a sense of how variable the effect sizes are relative to sampling error. Each study effect is marked with a box inversely proportional to study size, plus a wider interval for the CI that reflects sampling error. The mean effect (formulas given below) is shown as the center of a small diamond below the study CIs. The width of the diamond shows the 95% CI for the mean.

A “quick and dirty” test of agreement among the results asks whether any vertical line can be drawn across all the fixed-effect CIs in the forest plot. Often such a line falls near the mean effect. A vertical reference line may be added to show the point at which no difference exists for many T_i (for odds measures, a reference line may appear at 1). It is fairly unusual for meta-analyses to include histograms of results.

Example

Fig. 2 shows 95% fixed-effect confidence intervals in effect-size order for the standardized mean differences from TvG, specifically $T_i \pm 1.96\sqrt{v_i}$. Narrower intervals are from large studies, such as study 4. The TvG studies show positive effects overall, but they do not all show the same advantages for game-based instruction. Indeed, one effect size is -0.01 , and 8 intervals include zero, consistent with a null effect. In contrast the largest value shows almost a two standard-deviation difference in mean vocabulary scores. Also, no line can be drawn through all CIs for these studies, suggesting notable heterogeneity.

Fixed-effect or common-effect model

Model

The simplest model for a series of effect sizes is the fixed-effect (FE) model in Eq. (5), $T_i = \theta + e_i$, for $i = 1$ to k . All studies are assumed to have sampled from a single population and estimated one common θ . Given the diverse nature of studies in education and the social sciences this may be a rare event, but the fixed-effect model can also be adopted when the meta-analyst does not wish to generalize beyond the collected studies. Under this model all $\theta_i = \theta$, and variation among the T_i from different studies is presumed to be from sampling variation, which is captured by the v_i estimates. We can thus write

$$T_i \sim \text{Normal}(\theta, v_i), \text{ for } i = 1 \text{ to } k, \quad (6)$$

Fig. 2 The 95% confidence intervals for results of the TvG game-based learning studies.

and we can use either weighted-least-squares or maximum-likelihood methods to estimate θ as the minimum-variance unbiased inverse-variance weighted mean (Hedges, 1981) using

$$\bar{T}^{FE} = \frac{\sum_{i=1}^k w_i T_i}{\sum_{i=1}^k w_i}, \quad (7)$$

where $w_i = 1/v_i$ serves as the weight for study i . Because nearly all forms of v_i depend on the sample size n_i , the FE mean is very close to a sample-size weighted mean, and the influence of each effect size is greater when it is from a large sample.

The variance of $\bar{T}^{FE}$ is

$$\text{Var}(\bar{T}^{FE}) = \frac{1}{\sum_{i=1}^k w_i}. \quad (8)$$

The distribution of $\bar{T}^{FE}$ is also asymptotically normal, thus we can use the estimate and its variance to obtain a $100(1 - \alpha)\%$ confidence interval for the common θ as

$$\bar{T}^{FE} \pm z_{\alpha/2} \text{SE}(\bar{T}^{FE}). \quad (9)$$

Here the standard error of the mean is the square root of the variance in Eq. (8). A test of $H_0: \theta = 0$ is also available as $\bar{T}^{FE} \sqrt{\sum_{i=1}^k w_i}$ which is compared to critical values of the standard normal distribution. The **metafor** program for R (Viechtbauer, 2010) command `rma(T, v, method = "FE")` generates the values in Eqs. (8) and (9) and a set of associated statistics from the T_i and v_i .

Example of fixed-effect-mean estimation

For the 20 studies from TvG the fixed-effect estimate of the common population effect size is $\bar{T}^{FE} = 0.65$ standard-deviation units ($SE = 0.058$), leading to a 95% confidence interval for the common θ covering from 0.54 to 0.77. This interval does not include zero implying that game-based instruction is significantly superior to lecture-based instruction under the FE model.

Investigating between-studies variation

Because the forest plot of the TvG effect sizes shows heterogeneity, the effect sizes are probably not consistent across studies. In such cases if the meta-analyst is not devoted to using the fixed-effect model, they should model the between-studies differences reflected in the data.

Estimating τ^2

If the meta-analyst believes that the θ_i are not equal, the between-studies variance of the θ_i , denoted τ^2 , must be estimated. Many scholars have provided estimators of τ^2 ; Viechtbauer (2005) provides an excellent review of available methods. The earliest estimator (Hedges, 1983) is a simple method-of-moments estimator: Using the sample variance of the T_i (S_T^2) to reflect all observed variation, and the mean of the v_i ($\bar{v}$) to capture within-study variation, the between-studies variance is the difference

$$\hat{\tau}_{HE}^2 = S_T^2 - \bar{v}. \quad (10)$$

This estimator can take on negative values and thus it has been replaced by better-behaving estimators such as the restricted maximum likelihood estimator (REML, Thompson and Sharp, 1999), which is not shown here as it is iterative and cannot be written in closed form. We use the REML estimate below, obtained via `rma(T, v, method = "REML")` in **metafor**.

The index I^2

One other index of variation typically reported in meta-analyses is I^2 , a measure of the percent of observed effect-size variance that is true between-studies variation (Higgins and Thompson, 2002, Eq. 9). The program **metafor** calculates $I^2 = 100 \left[\frac{\hat{\tau}^2}{\hat{\tau}^2 + \bar{v}} \right] \%$, where $\bar{v}$ is a function of the v_i that captures sampling variation. Cutoffs of 25%, 50%, and 75% have been suggested for low, moderate, and high levels of true variation, but these are arbitrary.

Testing for homogeneity

Last, it is not necessary to test the hypothesis of no between-studies variance, that is $H_0: \theta_1 = \theta_2 = \dots = \theta_k$ or equivalently $H_0: \tau^2 = 0$, but it is easily accomplished using the weighted variance of the effect sizes (Hedges, 1983). The Q test is computed as

$$Q = \sum_{i=1}^k w_i (T_i - \bar{T}^{FE})^2 \quad (11)$$

where $w_i = 1/v_i$ and $\bar{T}^{FE}$ is the mean under the fixed-effect model from Eq. (7). The statistic Q follows an approximate chi-square distribution with $df = k - 1$ for k studies (though Hoaglin, 2016, points out problems with treating Q as a chi-square).

Example of between-studies variance assessment

We compute two variance estimates for the game-based learning studies. The method-of-moments estimator in Eq. (10) above (known as the HE estimator in *metafor*) is $\hat{\tau}_{HE}^2 = 0.157$ ($SE = 0.084$). The restricted maximum likelihood estimate is very similar: $\hat{\tau}_{REML}^2 = 0.155$ ($SE = 0.076$), with square root $\hat{\tau}_{REML} = 0.394$. If the θ_i values are normally distributed, most θ_i will fall in a range of about 1.54 standard-deviation units ($\pm 1.96 \times 0.394$) around the mean.

The value of I^2 for the TvG studies is 69%, near the benchmark for high variability. Over two-thirds of the observed variance in the effects reflects true differences among the populations, according to I^2 . Last, using Eq. (11), $Q = 60.6$, $df = 19$, and $p < .0001$ for the TvG data, also suggesting considerable between-studies heterogeneity.

Random-effects model

Model

Researchers typically design their studies to differ from others to increase their chances of successfully publishing something novel. This and other features of the process of science make it reasonable to expect that each study might have a unique effect θ_i . This is represented by the random-effects model,

$$T_i = \theta_i + e_i = \theta. + u_i + e_i \quad \text{for all } i. \quad (12)$$

This model is a special case of a multilevel model where the level-one (L1) model is $T_i = \theta_i + e_i$ and level two is given by $\theta_i = \theta. + u_i$ as seen in Eq. (12). Unlike in a typical multilevel model, the L1 variance in meta-analysis is not estimated using grouped data, because the within-study variance v_i is treated as known. The level-2 variance is the between-studies variance τ^2 introduced above that reflects variation among the true study parameters, the θ_i . It is also typical to treat the θ_i (or u_i) as normal, thus $\theta_i \sim N(\theta., \tau^2)$, where $\theta.$ is the mean of the θ_i .

Even when variation in true effects is anticipated, the meta-analyst often wants to estimate or test hypotheses about the mean $\theta.$ of the population of effects. Under random-effects assumptions all estimators and tests must address variation in the θ_i values. Assuming a normal distribution for the θ_i with mean $\theta.$ and variance τ^2 leads to the large-sample approximate result that $T_i \sim \text{Normal}(\theta., v_i + \tau^2)$, for $i = 1$ to k . We are no longer conditioning the variance of T_i on a common θ value. The mean effect size is typically estimated via either least-squares or maximum-likelihood estimation, and both require an estimate of the between-studies variance of the θ_i , τ^2 .

Investigating the mean effect

If the meta-analyst has adopted the random-effects (RE) model, the estimate of the overall mean effect size is typically obtained via the inverse-variance weighted estimator

$$\bar{T}^{RE} = \frac{\sum_{i=1}^k w_i^* T_i}{\sum_{i=1}^k w_i^*}, \quad (13)$$

where $w_i^* = 1/(v_i + \hat{\tau}^2)$ is the random-effects weight for study i using the estimate of τ^2 (e.g., $\hat{\tau}_{REML}^2$). The presence of both v_i and $\hat{\tau}^2$ in the weights reflects both within-study and between-studies variation. If $\hat{\tau}^2$ is much larger than the individual v_i , the weights for the T_i will be very similar across studies. In such cases $\bar{T}^{RE}$ is close to the unweighted mean.

The variance of $\bar{T}^{RE}$ reflects both sources of uncertainty – within-study uncertainty captured by v_i and between-studies variation represented by $\hat{\tau}^2$:

$$\text{Var}(\bar{T}^{RE}) = \frac{1}{\sum_{i=1}^k w_i^*} = \frac{1}{\sum_{i=1}^k (v_i + \hat{\tau}^2)^{-1}}.$$

The $100(1 - \alpha)\%$ random-effects confidence interval for the mean effect size θ , is

$$\bar{T}^{\text{RE}} \pm z_{\alpha/2} \sqrt{\text{Var}(\bar{T}^{\text{RE}})}. \quad (14)$$

The RE mean and the between-studies variance also can be used to estimate a “credible interval” that tells us where $100(1 - \alpha)\%$ of the population θ_i values are expected to lie. The interval $\bar{T}^{\text{RE}} \pm z_{\alpha/2} \hat{\tau}_{\text{REML}}$ is usually wider than the CIs given in Eq. (9) and Eq. (14) above.

Example of random-effects-mean estimation

The REML estimator of τ^2 for the TvG effects of 0.155 produces a mean effect of $\bar{T}^{\text{RE}} = 0.70$ ($SE = 0.109$). The random-effects SE of the mean is about twice the size of the fixed-effects SE of 0.058, producing a 95% confidence interval for the mean of 0.49–0.91. This interval’s location is shifted from where the FE interval was centered (at 0.65) and is also wider than the FE interval which ran from 0.54 to 0.77. As this RE interval also does not include zero and the mean is large, we still conclude that game-based instruction is superior to lecture-based instruction. However, the variation in the θ_i has increased our uncertainty – making us more unsure of where the mean effect is located.

We also use the REML variance estimate to create the credible interval including 95% of the population θ_i values, assuming normality of the θ_i . Using the RE mean, we compute $\bar{T}^{\text{RE}} \pm 1.96 \times \hat{\tau}_{\text{REML}}$, where $\hat{\tau}_{\text{REML}} = 0.393$. The credible interval covers 0.70 ± 0.77 or from -0.07 to 1.47 . Game-based instruction may have a small negative effect for some populations, but at the other extreme, effects of nearly 1.5 standard-deviation units are plausible. We can also use the normal distribution to estimate what portion of effects will be positive – for our data almost 95% of populations are predicted to have positive standardized mean differences under the RE model.

Explaining variation in effects

If considerable variation is found in the study results, or if the meta-analyst has prior hypotheses about the roles of coded study features, explanatory models are needed. Building on the asymptotic normal distribution for the effect sizes T_i , we can examine whether individual predictors or sets of predictors explain variation in effect sizes. Models like analysis of variance (for categorical predictors) and meta-regressions are available.

Meta-regression

Suppose that the meta-analyst wants to know whether study results have changed over time, or in relation to some other study feature. The model

$$\theta_i = \beta_0 + \beta_1 X_i \quad (15)$$

is a linear model where X (e.g., publication year) may explain part or all of the variance in the θ_i . Substituting this model into $T_i = \theta_i + e_i$, we obtain $T_i = \beta_0 + \beta_1 X_i + e_i$, which is a fixed-effect model with only sampling error. Alternately we may estimate the model under a mixed-model framework, adding a second error term u_i' to the model in Eq. (15), which accounts for any residual between-studies error not explained by all predictors. The analysis of linear models with predictors in meta-analysis has come to be called meta-regression.

Assuming independence of the T_i , we can use weighted least squares or other methods to estimate the key coefficient β_1 (or a set of β_j in the case of a multiple regression). We compute

$$\hat{\beta} = (X' \hat{\Sigma}^{-1} X)^{-1} X' \hat{\Sigma}^{-1} T$$

with variance $\text{Var}(\hat{\beta}) = (X' \hat{\Sigma}^{-1} X)^{-1}$ where X is a vector form of the X variable plus a column of ones to allow for an intercept (Hedges and Olkin, 1985). Also $\hat{\Sigma}^{-1} = \text{diag}(v_1, v_2, \dots, v_k)$ or in the case of a mixed model, $\hat{\Sigma}^{-1} = \text{diag}(v_1 + \hat{\tau}_X^2, v_2 + \hat{\tau}_X^2, \dots, v_k + \hat{\tau}_X^2)$, where $\hat{\tau}_X^2$ is the estimated variance of the between-studies residuals u_i' .

Together $\hat{\beta}$ and $\text{Var}(\hat{\beta})$ allow testing of the slope coefficient(s), and intercept if needed. A chi-square test of the predictor or set of predictors is also available, with $df = p$, the number of predictors (here $p = 1$). The weighted sum of squared residuals from this regression provides a chi-square test of whether X has explained all between-studies variance beyond sampling error.

Example of meta-regression

For the TvG data the model can be obtained from `metafor` using the fixed-effects command `rma(T, v, mods = ~ year, method = "FE")` for the predictor publication year. The estimated model is $\hat{T}_i = 36.7 - 0.018 \text{ Year}_i$, suggesting that the standardized mean difference drops by 0.18 every ten years. The earliest publication appeared in 2006 and the last in 2017, so the predicted decrease during the time frame of the studies is about 0.2 standard-deviation units. The standard error of the slope is $SE(b_1) = 0.018$, and the slope’s confidence interval covers from -0.054 to 0.018 , not a notable change.

The test for the slope is not significant ($Q(1) = 0.97$, $p = .33$) and residual variation from the model is considerable, with I^2 remaining at 69% and a significant residual test ($Q(18) = 59.6$, $p < .0001$). A mixed model (using method = “REML”) would

be a better choice so that we account for unexplained variation given the predictors. Year does not show significant predictive power when random effects are added, but for reporting we would use the mixed-model slope estimate of -0.014 ($SE = 0.037$).

ANOVA-like models

Another useful approach for examining multi-category predictors is the analogue to analysis of variance (ANOVA) described by Hedges (1982). As ANOVA is a linear model, estimates can be obtained using the meta-regression methods described above. However the ANOVA approach's separate within-group tests of homogeneity Q_g for each of the G groups help illuminate differences among study subgroups. Likelihood ratio and chi-square tests are available, and analyses can be done under fixed- or random-effects assumptions (though to test fit one must adopt the FE model).

Example of ANOVA

Table 1 shows results for the TvG studies grouped according to their gender composition. All groups showed significant treatment effects for game-based instruction, with the $k_1 = 2$ all-male samples showing the strongest effect with $\bar{T}_{.1} = 1.32$ standard-deviation units. All-female samples had a mean of 0.89, followed by mixed-gender samples and samples with unreported gender composition. All but the last mean differ from zero.

Three of the four subsets of studies showed little variation, and two of those had large effects (the all-male and all-female samples). This effect homogeneity allows us to say that the means for the single-gender samples and the studies with no gender information are common to all studies in those study subgroups. Mixed-gender samples showed a lower mean, and the greatest amount of spread. Unexplained variation remains within this study subset, and we interpret its mean of 0.63 as the average across the population of studies with mixed-gender samples. The between-groups test of differences due to gender composition was significant, with $Q(3) = 16.9$, $p < .001$.

Publication bias

A key threat to the validity of meta-analysis is publication bias (e.g., Dickersin, 1990; Smith, 1980), a tendency for collections of published studies to show a preponderance of significant results. Significant results can of course arise because researchers have examined effective treatments or strong relationships. But the documented tendency for journals to publish significant results, and for researchers to withhold non-significant ones, suggests that collections of studies may be filled with Type I errors. The published literature contains more significant results than would be reasonable if all results were published without regard to their significance, even when controlling for post hoc levels of power of the analyses.

A variant of this issue is reporting bias, where some research results within a published study are reported but others are not. Early studies of these biases (e.g., Coursol and Wagner, 1986) and explicit statements by journal editors confirm that both editors and referees are influenced by the strength of results. Selective reporting and related questionable research practices or QRPs (e.g., HARKing: Kerr, 1998; p hacking: Simmons et al., 2011; QRPs: John, Loewenstein and Prelec, 2012) make it critical for meta-analysts (1) to assess whether publication or reporting bias may be affecting their results (i.e., to "detect" publication bias) and if that seems likely, (2) to mitigate or adjust for it. A full treatment of publication bias can be found in Rothstein et al. (2005).

Detection of publication bias

Funnel Plot and Effect Asymmetry. The funnel plot (Egger et al., 1997) is a visual approach to detecting potential publication bias. The meta-analyst looks for asymmetry in a scatterplot of the effect sizes (typically displayed on the horizontal axis) versus a measure of their precision such as the sample size, the effect-size standard error (SE) or variance, or the inverse of the SE or variance. Sterne and Egger (2001) favor the standard error, plotted so that smaller values are near the top of the vertical axis.

If all effects arise from a single population, effects will be arrayed on either side of the mean, leading to symmetry in the plot. More dispersion is expected in less precise studies (near the bottom of the scatterplot). However, heterogeneity can result from many reasonable sources of variation (e.g., different durations or intensities of treatments, diversity in the studied samples), chance, true heterogeneity in effects, poor study design or analysis, or bias in reporting (Sterne et al., 2011). The funnel plot is a popular approach to bias detection in spite of the need to decide on asymmetry based only on one's judgment. Tests of asymmetry (e.g., by Egger et al., 1997) reduce this concern.

Table 1 Mean effect size and group-level analyses by gender composition of samples.

Sample gender composition	k_g	$\bar{T}_{.g}$	$SE(\bar{T}_{.g})$	z_g	$p(z_g)$	95% confidence limits		$\hat{\tau}_{REMLg}$	Q_g	$p(Q_g)$
						Lower	Upper			
All male	2	1.32	0.272	4.86	<.0001	0.79	1.85	0.29	2.22	0.14
All female	2	0.89	0.207	4.32	<.0001	0.49	1.30	0	0.99	0.32
Mixed gender	13	0.63	0.133	4.74	<.0001	0.37	0.89	0.38	34.9	0.0005
Unspecified	3	0.43	0.223	1.95	.051	-0.00	0.87	0.29	4.59	0.10

Fig. 3 Funnel plot with fixed-effects contours.

Comparisons of Published and Unpublished Studies. A very common approach (e.g., [Smith, 1980](#)) is to compare the results of published and unpublished studies. An indicator of publication type can be added to a meta-regression. This approach requires that unpublished reports be collected, which is considered state-of-the-art for data collection.

Example. [Fig. 3](#) shows a scatterplot of our example effects made under the fixed-effects assumption. Following Thompson and von Gillern (p. 20) we use $\sqrt{v_i}$ as the precision measure. Contour curves allow the meta-analyst to identify effects that are not consistent with an underlying model of homogeneity ([Peters et al., 2008](#)). Two extreme studies are seen to the left and four to the right of the contours but the effects appear to be largely symmetrical. However, Egger et al.'s test reveals a significant degree of asymmetry ($z = 2.21$, $p = .03$).

We next compare results from published and unpublished sources. A mixed-effects meta-regression estimated a nonsignificant difference between means from the 16 published and 4 unpublished sources of 0.14 standard deviations ($SE = 0.29$). Published studies show a larger mean of 0.72 versus 0.58 for effects from other sources, consistent with the idea that smaller effects are less likely to be published.

TvG's original meta-analysis used Bayesian methods to examine this difference. [Fig. 4](#) shows the posterior densities for the means and standard deviations of the published and unpublished studies. Bayesian posterior distributions show where the bulk of the population effects might lie if we treat all model parameters as random quantities ([Sutton and Abrams, 2001](#)). The posterior density of the mean for the unpublished studies on the left in the upper panel of [Fig. 4](#) has lower mode and mean values than that for the published studies, and is considerably more dispersed (with $SD = 0.22$ vs. 0.13 for published sources). In the lower panel the posteriors of the SDs τ differ dramatically and show that unpublished studies (with a mode of zero) have minimal between-studies variance compared to the more-dispersed published studies.

Adjusting for publication bias

If potential publication bias is seen, it is common to adjust for its presence. Adjustments usually shrink estimates toward zero, because publication bias favors larger effects as seen in TvG. A popular adjustment method from [Duval and Tweedie \(2000\)](#) – the trim-and-fill technique – keys off of symmetry in the funnel plot. The mathematical details are too complex for this chapter, but in short, the plot is populated with the original effects plus hypothetical points that might have been unreported, making the funnel more balanced. Then a new mean effect size and confidence interval are computed. [Fig. 5](#) shows the trim-and-fill based on the fixed-effect model. Four negative effects are added, and the mean is adjusted downwards to 0.52 ($SE = 0.054$) from the original mean of 0.65. Under the random-effects model the trim-and-fill analysis does not add any data points, and the mean is not adjusted.

Other adjustment techniques use selection models that adjust based on hypothesized chance of publication, such as “all results with $p < .05$ will be published, but only half of studies with $p > .05$ will appear.” [Hedges \(1984\)](#), [Iyengar and Greenhouse \(1988\)](#), and [Vevea \(Vevea and Hedges, 1995; and Vevea and Woods, 2005\)](#), among others, have modeled selection of effect sizes.

Other summaries

A variety of other overall summaries are available for meta-analysis. We advise avoiding summaries based on p values, including the popular failsafe N ([Becker, 2005](#); [Rosenthal, 1979](#)). These address an overly general hypothesis ([Becker, 1987](#)) and inherently confound information about sample size and effect size.

Fig. 4 Posterior distributions of the means θ . and standard deviations τ for studies grouped by publication status.

Fig. 5 Trim-and-fill plot with fixed-effect contours.

Advanced meta-analysis methods

Advanced meta-analytic techniques provide sounder or more informative analyses for some common meta-analytic situations. We mention just a few.

Dependence in meta-analysis

One prevalent complexity of primary research is dependent outcomes (Becker, 2000). Ignoring dependence can lead to higher levels of Type I error (Riley, 2009), and studies with many correlated outcomes can unduly influence a synthesis if those outcomes are treated as independent.

Approaches to dependence include ignoring it (if only a few studies in a large synthesis report multiple outcomes), creating subsets of independent results, and data reduction, which can lead to loss of information on within-study differences. Raudenbush et al. (1988) were the earliest to propose multivariate effect-size analyses, and robust-variance based methods can also be used (Hedges et al., 2010). Multiple comparison groups within and across studies can be addressed via network meta-analysis (Lu and Ades, 2004) which links sets of studies of multiple treatments to show the evidence on all conditions that have been compared.

Bayesian approaches

Bayesian analyses incorporate the meta-analyst's prior beliefs with the accumulated study effects and provide extensive information about the potential distributions of study parameters. Bayesian posterior distributions show where each population of effects – from individual study effect sizes to overall means and between-studies variances – might lie. These densities provide richer detail on location, dispersion, and shape than simpler credible intervals or CIs. While full explication of Bayesian analyses is beyond the scope of this chapter, we note that computational advances have made these analyses more accessible. The program **bayesmeta** (Roever, 2020), used by TvG and to obtain the plots shown above, is one example.

Interpretation and reporting of results

Detailed guidance for reporting meta-analyses is provided in numerous sources, including PRISMA, APA's Meta-analysis Reporting Standards (Appelbaum et al., 2018), the online Cochrane Handbook (<https://training.cochrane.org/handbook/current/chapter-iii>), and the Stroup et al. (2000) guidelines for observational studies. We mention only points that we view as vital.

A quality report is complete, transparent, and helps the reader understand what was done and the relevance of the results. The goal is to craft a report that would allow for replication of the review. Meta-analysts must give details of the process (inclusion and search rules, data-evaluation quality, etc.) as well as of the results. Reporting the PRISMA flow chart is a must. Reports should include tables of coded features and their reliabilities, and a table of study results and coded features. We advocate for listing all effect sizes, either in a table or forest plot. With the advent of open science this task has become somewhat easier.

The reviewer should begin by describing the problem that was formulated and noting whether the collected studies matched the target population. Matt and Cook (2009) argued that considering the universe of interest to the meta-analyst (the populations of U's, T's, O's, and S's) is key to understanding how far meta-analysis results can be generalized. If the studies match the target population, the meta-analyst can report what the effect-size analyses have revealed without conditions. If the studies do not map well onto the target, the meta-analyst should describe any gaps – in sample composition, outcomes or relationships examined, and treatment instantiations; these are candidate areas for future research. Of late gap maps have become popular for this purpose. Meta-analyses should report what is not known, as well as what is known.

A primary part of interpretation is to evaluate the magnitude of the typical effect size. Meta-analysts should contextualize effect magnitudes in the domain of interest rather than focusing on significance. Reports often default to using Cohen's (1988) rules of thumb, but even Cohen argued that his benchmarks were not universal. An effect of 0.16 may be small according to Cohen but seem large in a field where treatments rarely lead to strong effects.

A second goal is to convey an understanding about dispersion in results. Measures of uncertainty should be reported for all point effect-size estimates, and reports of random-effects meta-analysis should include not only confidence intervals for means, but also statements about the potential range of the distribution of population effects using credible intervals. Graphical methods are extremely useful in this regard. Minimal dispersion between studies suggests that the observed mean effects apply widely in the population, that is, effects do not depend on moderators. Here Cook's (1993) concept of heterogeneous irrelevancies is useful. Cook argues that nonsignificant moderator analyses support broader generalizations than significant ones, by identifying features that do not matter to the size of an effect or to its variability. If findings depend on participant, outcome, or intervention features, their applicability is constrained. The meta-analyst should report on all moderator analyses that were done regardless of significance. Omitting nonsignificant results adds reporting bias to a literature that may already suffer from it.

A complete report also describes the quality of evidence in the studies such as biases or method-related differences. Thompson and von Gillern reported a slightly larger mean of 0.71 for randomized studies, versus 0.61 for other studies. While not significant the 0.10 difference is not far from Lipsey and Wilson's (1993) finding of a 0.05 SD advantage for randomized studies in 74

syntheses. Visualizations of the degree of biases can be produced by software like **robvis**, an R package (McGuinness and Higgins, 2020). The meta-analysis report should also cover limitations in the review itself (Higgins et al., 2013) such as issues with reliability of coding or publication bias.

Finally, review results should be placed into the broader context of research and practice by connecting to past reviews in the field, if any, and to dominant theories relevant to the review. Meta-analytic findings that conflict with theoretical predictions raise questions about elements of relevant theories. Gaps (as mentioned above) and limitations can lead to recommendations for future research.

In many fields meta-analyses will have implications for practice and policymaking. Meta-analyses now form the foundation of evidence-based medicine. Government agencies such as the Agency for Healthcare Research and Quality use meta-analyses to influence physician decision making. Meta-analyses are critical to the U. S. Food and Drug Administration's (FDA) drug-approval process, as evidenced by the FDA's development of a draft Guidance document for the use of meta-analyses (Food and Drug Administration, U.S. Department of Health and Human Services, 2018). Likewise, the U. S. Department of Education's What Works Clearinghouse's primary focus is to scrutinize educational-intervention studies, and where justified, to synthesize them. While meta-analyses conducted by individuals may not have the immediate impact of government funded works, by conducting high quality meta-analyses and setting out the lessons learned for practice, all meta-analysts can reach toward that goal.

INDEX

Notes

Cross-reference terms in *italics> are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space). Readers are also advised to refer to each article for additional cross-references – not all of these cross-references have been included in the index cross-references.*

The index is arranged in set-out style with a maximum of three levels of subheading. Major discussion of a subject is indicated by bold page numbers. Page numbers suffixed by t, f, and b refer to Tables, Figures, and Boxes respectively. *vs.* indicates a comparison.

The index entries are presented in word-by-word alphabetical sequence in which a group of letters followed by a space is filed before the same group of letters followed by a letter. For example, entries beginning 'air density' are alphabetized before 'aircraft.' Prefixes and terms in parentheses are excluded from the initial alphabetization.

 central line of MM design in TePP project
 12:629–631
 challenges in conducting large-scale MM
 studies in 12:627–628
 in changing global arena 1:480–487
 co-citation analysis 4:551–553
 and cognitive aging 6:515–518
 as complex system 9:28–29
 context in Thailand 4:491–492
 covid-19 and right to 1:407–409
 datafication in 1:674–675
 democracy and 2:8–12
 in developing countries
 broad overview 1:209–210
 Chile 1:208
 development decades five and six 1:211
 fourth decade 1:210–211
 Ghana 1:208–209
 knowledge society 1:212–213
 Mexico 1:208
 partnerships 1:211–212
 poverty reduction strategy papers 1:212
 results-based lending 1:213–214
 third development decade 1:207
 two development decades 1:206–207
 Zambia 1:209
- development, South Asia 1:427–428
- diplomacy 8:205
- and disability, developments in special
 needs 9:429
- disability and rate of returns on investment
 in 9:51
- disability biases and change in economic
 household decision in 9:52–54
- disability related extra costs in 9:55
- disability studies in
 intersectional case-study 9:252–253
 intersectionality 9:249–252
 leveraging intersectionality 9:254–256
 through disability youth activism
 9:321–323
- disciplined study of cases in 12:85–86
- discourse analysis 12:29
- disenfranchised individuals and groups in
 Hong Kong and Mainland China,
 research on, 0 of 7:398
- diversity, democracy, and social justice in
 2:313–319
- and economic development 1:53
- embedding disability youth activism within
 inclusive education 9:323–325
- emergence of private corporate and
 philanthropic actors in 1:392–394
- emergence of WB as prominent actor in
 education for economic
 development 1:480–482
- English as medium of instruction and
 research in
 2008 White paper on Norwegian
 language policy 1:376–377
 academic publishing 1:376
 example from Tanzania 1:377

- higher rewards for academic publications in English 1:376
- Norwegian researchers defending our language as language of research 1:377
- from one colonial language to other in Rwanda 1:375
- prestige planning 1:377–378
- private primary schools 1:373
- rhetoric of English and development 1:373–374
- situation in India 1:374–375
- situation in Nordic countries 1:375
- strengthening of government primary school 1:373
- ethnography 12:28–29
- ethnonationalism 2:77–78
- external aid for 1:443
- financing of 1:421
- first nations & indigenous identities in 9:151–158
- formulating and implementing workable language of 3:66
- fundamental approach 1:513–514
- Gabriel Boric's proposals 2:80–81
- gender equality and measurement 2:69–71
- globalism 2:78
- globalization and public funding of 1:441–443
- globalization and shifting geopolitics of education role in bridging digital divide 1:162
- glance at facts 1:157–158
- highlights from recent empirical research 1:160–162
- inequality of digital access 1:157–158
- inequality of digital use and online skills 1:158
- theories of digital divide 1:158–160
- globalization as spaces and flows 1:2–4
- under globalization
- IB and shifting geopolitics of 1:347–352
- grounded theory 12:27
- research in 12:111–119
- studies in 12:116
- history
- curriculum studies 7:118–119
- denominational roots of cultural configuration of 7:119–121
- national curricula and national epistemologies 7:121–122
- national discourses, international research and 7:122–124
- as human capital 7:310–311
- and human development 1:54–55
- and human rights 1:56–57
- humanizing language and literacy in 10:346–357
- Husserl, Heidegger & Merleau-Ponty 12:131–133
- identifying document database for bibliometric review 4:547–549
- and identity 9:486
- illustrative applications of clustering in 14:632–634
- implementation of interdisciplinary approach in 7:274–277
- implications of globalization for 1:7–8
- inclusive approach to 4:402
- increasing competitive nature of 7:292
- insistence on disability studies in 9:509–510
- integrating art and artistic practices into mixed methods studies in 12:705–707
- centering artistic practices in a mixed methods study 12:707
- embedding art within other methodological approaches 12:705–707
- interdisciplinary conceptions 7:268–272
- and practices in Quebec education 7:270–272
- and international development 2:65–68
- intervention strategies to overcome barriers 9:54
- for just, utopistic, transition 1:25–26
- keyword co-occurrence analysis 4:553
- knowledge 2:75–77
- language of education and literacy issues, English 3:65
- leadership for 4:30–31
- learn from populism 1:653–655
- for liberation 7:358
- living schools and purpose of 7:352–354
- logics 7:268–270
- machine learning in 6:86–89
- market 1:64–67
- Max van Manen 12:136–138
- methodological challenges in evaluating cost benefits of 9:55–57
- methodology 9:487
- mixed methods
- case study in 12:546–547
- and multimethod research in 12:361–371
- within multiple geographies of Asia-Pacific 1:414–417
- civic and social education 1:415–416
- international assessments and education divide 1:414–415
- myths about special 9:279–281
- narrative inquiry 12:27–28
- NDIS and 9:447–448
- negation of racial disparities by field of special 9:243
- neo-colonialism and 1:686
- neoliberalization of 1:63–64
- new pathways in
- implications on framework conditions 8:61–62
- learning pathways 8:58–61
- for new world order 1:488–489
- in Nigeria
- conceptualizing englishization 3:61–66
- educational policies and English in Nigeria 3:63–64
- PAR 12:29–30
- as part of colonialist imperialist project 1:685–686
- and participatory democracy
- interrupting democratic ideal 2:228–229
- schooling and democratic citizenship 2:230–231
- schooling as affective violence 2:232–233
- whiteness against participatory democracy 2:231–232
- pedagogical phenomenology 12:139
- phenomenology 12:26–27
- and methodology 12:134–138
- philosophy to educational research 12:133–134
- planning, technology and language choice in 10:818–821
- design solution 10:820
- end-users 10:820
